ABSTRACT

X-ray and infrared surveys provide efficient, and to some degree complementary, means of detecting and characterising Active Galactic Nuclei (AGN), with the infrared also providing an important probe of the host galaxies. To this end we combine the deepest X-ray survey from the Chandra Deep Field-South (CDF-S) ‘7-Ms’ survey (Luo et al. 2017) with the deepest mid-infrared (5.6 μm) image from the JWST/MIRI Deep Imaging Survey (MIDIS) in the Hubble Ultra-Deep Field (HUDF) to study the infrared counterparts and point-source emission of 31 X-ray sources with a median, intrinsic, rest-frame X-ray luminosity of $\log_{10}(L_{\text{Xc}}^{0.5-7\text{keV}}) = 42.04 \pm 0.22$ erg s^{-1} . The sample includes 24 AGN with a redshift range, as set by the X-ray detectability, of $z \approx 0.5-3$, with the bulk of the sources lying at $z \approx 1-2$, i.e. at around the epoch of Cosmic Noon. Through a **multi-wavelength morphological decomposition**, employing three separate classifications (visual, parametric and non-parametric) we separate (where present) the luminosity of the point-like AGN component from the remainder of the host-galaxy emission. The unprecedented mid-infrared sensitivity and imaging resolution of MIRI allows, in many cases, the direct characterisation of point-like (i.e. unresolved) components in the galaxies’ emission. We establish a broad agreement between the three morphological classifications. At least 70% of the X-ray sources, including some classified as galaxies, show unresolved emission in the MIRI images, with the unresolved-to-total flux fraction at rest-frame 2 μm ranging from ~ 0.2 to ~ 0.9 . At high X-ray luminosities ($\log_{10}(L_{\text{Xc}}) > 43$ erg s^{-1}) we derive a consistent rest-frame near-infrared 2 μm point-source luminosity to that derived for local AGN, whilst at lower X-ray luminosity we identify an excess in the 2 μm emission compared to pre-JWST studies. We speculate this offset may be driven by a combination of Compton-thick AGN components and nuclear starburst, merger driven activity. Our observations highlight the complex nature of X-ray sources in the distant Universe and demonstrate the power of JWST/MIRI in quantifying their nuclear infrared emission.

Key words. Galaxies: high-redshift, Galaxies: active, Galaxies: structure, X-rays: galaxies

1. Introduction

Since the discovery that the cosmic X-ray background was isotropic (Fabian & Barcons 1992), there followed major interest in determining the contributions of discrete source popula-

tions, as a function of X-ray energy. These studies combined the results from all-sky catalogues which sampled the discrete sources at limited X-ray sensitivity, with deeper serendipitous samples of sources scattered around the sky e.g. using Chandra and XMM-Newton. These studies (Cappelluti et al. 2017) have resolved more than 90% of the background below 10 keV into

* ORCIDiDs listed on final page

different classes of AGN, including unabsorbed sources, partially obscured sources and Compton thick sources. At energies greater than 10 keV the fractions of the AGN population change in favour of the obscured sources. Although there is a correlation between X-rays and the mid-infrared (MIR), it was shown that using a MIR colour selection criterion based on the WISE all sky survey (e.g. Stern 2015), missed a significant fraction of AGN detected in hard X-ray by NuSTAR and XMM-Newton (Mateos et al. 2012). Since the Mid Infrared Instrument (MIRI; Wright et al. 2023) on board JWST offers so much greater sensitivity and spatial resolution compared with all previous mid-IR facilities, it is now possible to spatially resolve high redshift ($z > 1$) galaxies in the mid-infrared (Boogaard et al. 2024; Costantin et al. 2024).

The contribution of an AGN to a galaxy’s spectral energy distribution (SED) peaks at mid-infrared wavelengths, especially for dust-obscured sources whose non-stellar emission is reprocessed through hot and warm dust emission (Hickox & Alexander 2018). With MIRI observations it is thus possible to isolate the unresolved AGN-heated dust emission in the rest-frame near-infrared spectral range at much higher redshifts than is possible with NIRCам (Tanaka et al. 2024). At rest-frame 2–3.5 μm , type 1 (unobscured) nearby AGN show a strong correlation between the hard (2–10 keV) X-ray and the non-stellar (unresolved component) luminosities, while type 2 lie below the correlation due to torus obscuration effects (see e.g. Kotilainen et al. 1992; Alonso-Herrero et al. 1997; Burtscher et al. 2015). Thus, it is interesting to examine a sample of X-ray selected sources (AGN and galaxies, see below) detected in the MIRI Deep Imaging Survey (MIDIS; Östlin et al. 2024) field. This provides new information regarding the presence or absence of an AGN dust heated nuclear component and its contribution with respect to the host galaxy emission, even in low X-ray luminosity galaxies where part of the X-ray emission may have stellar origins (e.g. X-ray binaries, shocks) and thus providing insights into the nature of the host galaxy (e.g. Gao et al. 2003; Barrows et al. 2024).

In this paper, we present a morphological analysis of a sample of 31 X-ray-selected sources in the MIDIS field with the goal of estimating the unresolved emission associated with AGN heated dust. In Section 2 we present the parent X-ray catalogue from the Chandra 7-Ms survey before outlining the other observations and data reduction in Section 3. In Section 4 we define the sample of X-ray sources in the MIDIS survey and present the analysis of multi-wavelength JWST observations with the associated results and discussion in Section 5, before summarising our main conclusions in Section 6. Throughout the paper, we assume a Λ CDM cosmology with $\Omega_m = 0.3$, $\Omega_\Lambda = 0.7$, and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. All quoted magnitudes are on the AB system and stellar masses are calculated assuming a Chabrier initial mass function (IMF) (Chabrier 2003). All uncertainties reported on median values are bootstrapped uncertainties.

2. The sample: CDF-S X-ray sources

We use the X-ray source catalogue from the Chandra Deep Field-South (CDF-S) ‘7-Ms’ survey (Luo et al. 2017)¹ to identify the infrared (IR) counterparts to galaxies with detected X-ray emission in the MIDIS field. To date, this set of observations comprises the deepest X-ray survey conducted anywhere in the sky, and hence represents the most sensitive search for AGN X-ray

emission, outside of observations utilising gravitational lensing to augment the luminosity and redshift reach (e.g. Bogdán et al. 2024).

CDF-S covers a roughly circular region of sky, with total area 484 arcmin²; it encompasses, and is roughly concentric with, the GOODS-S survey region; hence it also contains the HUDF, and thus MIDIS, which are located towards the central, most sensitive part of CDF-S. The CDF-S source survey is flux-limited, with full-band (0.5–7 keV) point-source threshold ranging from $< 3 \times 10^{-17} \text{ erg cm}^{-2} \text{ s}^{-1}$ close to the survey centre, to $> 10^{-15} \text{ erg cm}^{-2} \text{ s}^{-1}$ near to the survey perimeter (Luo et al. 2017, Fig. 29). The main source catalogue contains 1008 sources above the detection-significance threshold. There is a supplementary catalogue of 47 lower-significance sources included due to proximity to bright near-infrared (NIR) candidate counterparts. We refer to the main-catalogue sources by the running number (‘XID’) assigned by Luo et al. (2017), while for the supplementary list we prefix the XID with ‘S-’ to avoid ambiguity. As detailed in Luo et al. 2017, the main catalogue has a median redshift of $z = 1.2 \pm 0.05$ with a 16th–84th percentile range of $z = 0.52$ –2.32. The median intrinsic (i.e. rest-frame), absorption-corrected, X-ray luminosity of the catalogue is $\log_{10}(L_{\text{Xc}}^{0.5-7\text{keV}}) = 42.5 \pm 0.06 \text{ erg s}^{-1}$ with a 16th–84th percentile range of $\log_{10}(L_{\text{Xc}}^{0.5-7\text{keV}}) = 41.1$ –43.8 erg s^{-1} . Whilst the median intrinsic absorption column density is $\log_{10}(N_{\text{H}}) = 22.7 \pm 0.04 \text{ cm}^{-2}$ with a 16th–84th percentile range of $\log_{10}(N_{\text{H}}) = 21.8$ –23.5 cm^{-2} . The Chandra images have a spatial resolution ~ 1 arcsec, varying with photon energy and off-axis angle (e.g. Primini et al. 2011).

The source positions reported by Luo et al. (2017) are adjusted by $\Delta\text{RA} = +128 \text{ mas}$, $\Delta\text{Dec} = -288 \text{ mas}$, as derived by Lyu et al. (2024) for the Systematic Mid-infrared Instrument Legacy Extragalactic Survey (SMILES; PI: G. Rieke, #1207), to bring them into alignment with the GAIA reference coordinate system adopted for the JWST (and reprocessed HST) images (Gaia Collaboration et al. 2021). We cross-match the updated Chandra positions for the X-ray sources with the footprint of the MIDIS Survey, as shown in Figure 1. For our analysis we require the X-ray source to be covered by at least the F560W filter in the MIDIS survey, ensuring observed-frame mid-infrared is sampled. This results in a sample of 31 X-ray sources for which Luo et al. (2017) classify 14 as ‘AGN’, and 17 as ‘galaxy’. The label of ‘galaxy’ indicates that through the multi-wavelength analysis carried out to date, no AGN component has been identified. However, using somewhat different criteria, Lyu et al. (2022), in their (pre-JWST) AGN catalogue, classify 23 of these X-ray sources as ‘AGN’: all those previously so classified, plus 9 from the ‘galaxy’ category. In addition, the recent JWST/MIRI SMILES AGN survey (Lyu et al. 2024) yields one further AGN classification. Hence, the current tally is 24 AGN and 7 Galaxies. These AGN/Galaxy assignments are listed in Table 1. All 31 MIRI sources were previously detected at mid-IR (Spitzer) and near-IR/visible (HST) wavelengths; hence their basic X-ray/IR properties have already been established (e.g. Luo et al. 2017, Lyu et al. 2022). Six of the highest-flux Chandra sources have X-ray spectra reported by Liu et al. (2017). These same six sources were also detected by XMM-Newton (Ranalli et al. 2013)².

For 97% (30/31) of the MIDIS sources that originate from the main CDF-S catalogue, we compare their properties to the overall CDF-S survey as presented above. We

¹ Downloaded from the online CDS VizieR catalogue server: <https://vizier.cds.unistra.fr/viz-bin/VizieR-3?-source=J/ApJS/228/2>

² A seventh, low significance, source in the XMM-Newton catalogue of Ranalli et al. (2013) was noted by them as ‘probably spurious’, and we find no reasonable MIRI-F560W counterpart.

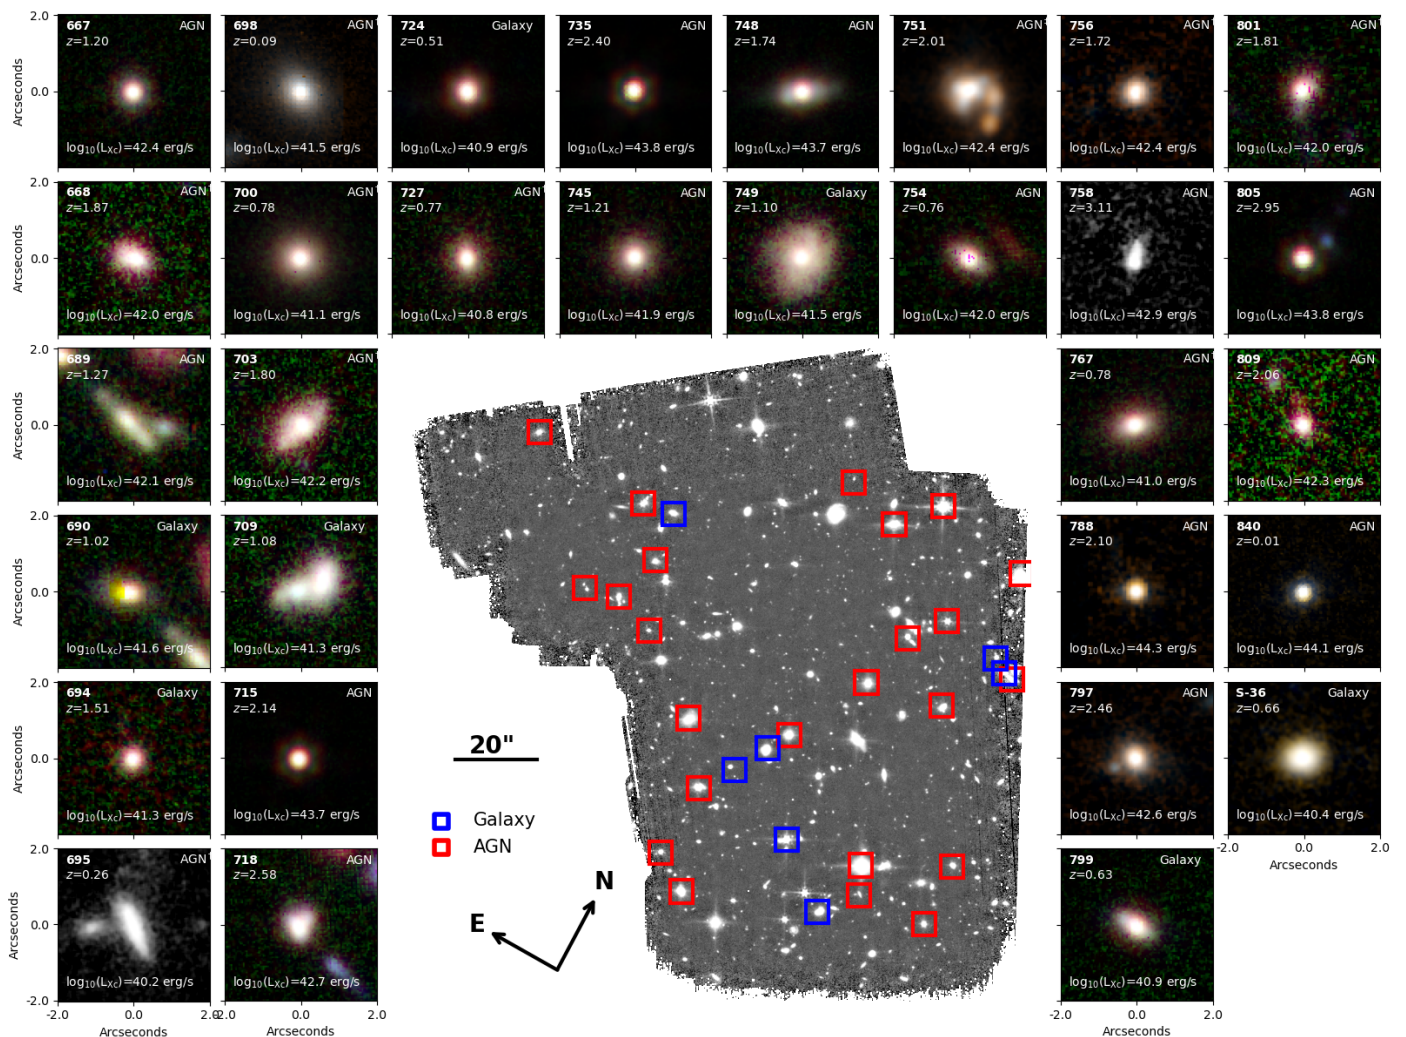

Fig. 1. The MIDIS MIRI 5.6 μm image in the HUDF (*centre*) with $4''.0 \times 4''.0$ false colour maps (F1000W/F770W/F560W as R/G/B) for the 31 X-ray-detected sources. We highlight the positions of sources classified as Galaxy (blue squares) and AGN (red squares) in the 5.6 μm image. In each false colour image, we label the source ID from Luo et al. (2017), spectroscopic redshift, absorption-corrected intrinsic 0.5–7.0 keV luminosity (L_{Xc}) and the object class (AGN or Galaxy). ID 695 and ID:758 are shown as monochromatic F560W images due to the high noise levels in the F1000W image.

establish a median redshift of $z = 1.3 \pm 0.2$ with a 16th–84th percentile range of $z = 0.65$ –2.49. The thirty sources have a median absorption-corrected X-ray luminosity of $\log_{10}(L_{\text{Xc}}^{0.5-7\text{keV}}) = 42.1 \pm 0.21 \text{ erg s}^{-1}$ and column density of $\log_{10}(N_{\text{H}}) = 22.5 \pm 0.3 \text{ cm}^{-2}$, with a 16th–84th percentile range of $\log_{10}(L_{\text{Xc}}^{0.5-7\text{keV}}) = 41.0$ –43.7 erg s^{-1} and $\log_{10}(N_{\text{H}}) = 21.7$ –23.2 cm^{-2} respectively. This indicates that there is not a substantial difference in these properties between the MIDIS sample and the parent catalogue. Comparing the number of X-ray sources and the sky area for MIDIS and the full CDF-S: MIDIS occupies $\sim 1\%$ of the CDF-S, but has $\sim 3\%$ of the X-ray sources; this can be understood in terms of MIDIS lying in a relatively high sensitivity part of CDF-S.

3. Observational Data

To analyse the AGN component of the X-ray detected galaxies in the MIDIS deep survey, we utilise deep multi-wavelength observations from public HST and JWST surveys in combination with those from the MIDIS survey of the HUDF, as we now describe.

3.1. MIDIS

A full description of the MIRI Deep Imaging Survey observations and data reduction is given in Östlin et al. (2024). In short, between December 2022 and December 2023, 52 hours of F560W and 10 hours of F1000W imaging were obtained in the HUDF. All observations were coherently reduced using a modified version of the official JWST pipeline³, version v1.12.3 (CRDS_CONTEXT = 1137), with additional routines to deal with cosmic-ray showers and background variations. As per the NIR-Cam and HST observations, each exposure was aligned to Gaia DR3, co-added and drizzled to a final pixel scale of $0''.04$. In Figure 1 we show the final 5.6 μm mosaic from MIDIS, with a 5σ point-source depth of 28.6 mag (0.013 μJy) (Östlin et al. 2024), highlighting the unprecedented depth and resolution of the MIDIS observations. This is comparable to the depths of the JWST Advanced Deep Extragalactic Survey (JADES; PI:

³ <https://github.com/spacetelescope/jwst>

⁴ We note this pixel scale is different to that presented in Östlin et al. (2024) to be consistent with the ancillary observations used in our analysis.

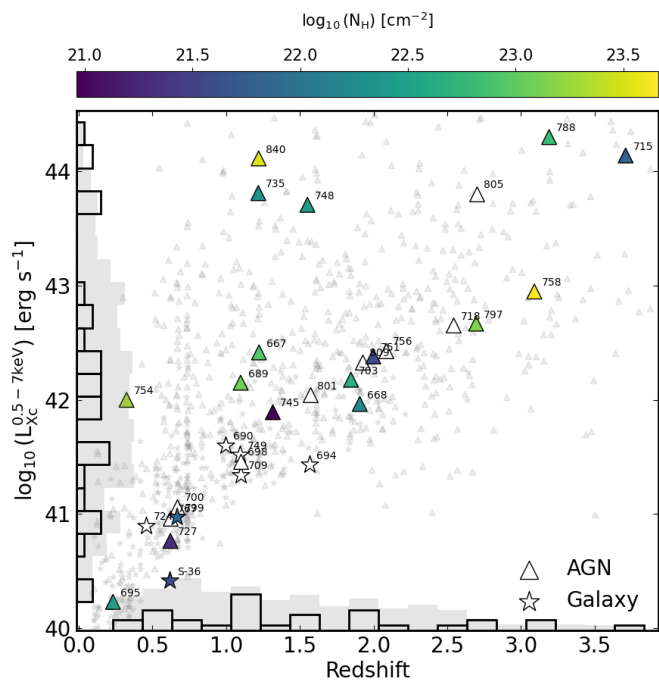

Fig. 2. Absorption corrected X-ray (0.5–7 keV) luminosity as a function of redshift for the 31 X-ray sources in the MIDIS survey coloured by column density (N_{H}). In the background we show the X-ray emitting sources identified by Luo et al. (2017) in the 7Ms survey. We show the distribution for the MIDIS sources (black histogram) and 7Ms sources (grey histogram, scaled down by a factor 10) on each axis. A clear trend of increasing X-ray luminosity with redshift is apparent, as expected for a flux-limited sample.

D. Eisenstein, #1180) NIRC*am* observations (Eisenstein et al. 2023) with a F444W 5σ point-source depth of 29.2, whilst being significantly deeper than the wide-area observations from SMILES with a 5σ point-source depth of 25.6 at $5.6 \mu\text{m}$.

3.2. HST and JWST

We collate multi-wavelength JWST and HST observations in the HUDF from the DAWN JWST Archive (DJA)⁵, as described in Gillman et al. (in prep.). Briefly, these observations cover the full observed-frame spectral energy distribution from 0.4–4.8 μm with the HST (F435W, F606W, F775W, F814W) and NIRC*am* (F090W, F115W, F150W, F200W, F210M, F335M, F277W, F356W, F410M, F444W, F460M, F480M) filters as well as the MIRI F770W filter at 7.7 μm . The observations, taken from a variety of public JWST surveys (e.g. JADES; Eisenstein et al. 2023, First Reionization Epoch Spectroscopically Complete Observations (FRESCO; PI: P. Oesch, #1895) Survey; Oesch et al. 2023, SMILES; Alberts et al. 2024) were coherently reduced using the GRIZLI software (Brammer et al. 2022), which builds upon the level-2 data products from the STScI archive⁶ and incorporates additional routines to deal with diagonal striping, cosmic rays and stray light identified in some exposures (see Boogaard et al. 2024; Gillman et al. 2023, 2024). We align all images to the same World Coordinate System (WCS) reference using the Hubble Legacy Field (HLF) catalogue in Whitaker et al. (2019) based on Gaia DR3 (Gaia Collaboration et al. 2021).

⁵ <https://dawn-cph.github.io/dja/index.html>

⁶ <https://mast.stsci.edu/>

The final mosaics are co-added and drizzled to a $0''.04$ pixel scale (Fruchter & Hook 2002) for all JWST and HST filters.

4. Analysis

To study the properties of the point-source (AGN) component of the X-ray detected sources in the MIDIS survey, we first identify the MIRI F560W and F1000W counterparts and characterise their multi-wavelength properties prior to employing a two-dimensional spatial decomposition routine to separate the AGN component and host galaxy.

4.1. MIRI Counterparts

To identify the MIRI counterparts, we cross-match the sample of 31 X-ray sources, with updated positions (see Section 2) to THE FARMER catalogue, as presented in Gillman et al. (in prep.). THE FARMER catalogue, which utilises the deep F560W image from the MIDIS survey as the detection image, employs a model-based forced photometry approach to define the multi-wavelength fluxes of the detected sources from 0.4–10 μm .

To identify a MIRI counterpart to each of the 31 sources in the MIDIS field of view, we require a counterpart search radius of $1''.5$. As shown in Figure 1, we identify X-ray sources across the full extent of the MIDIS footprint, with a median X-ray to 5.6 μm offset of $\delta r = 0''.25 \pm 0''.05$ arcseconds and a 16–84th percentile range of $\delta r = 0''.11 - 0''.48$. Comparing δr for each source with the corresponding X-ray positional error radius (1 standard deviation ($\approx 68\%$ confidence level), σ_r , Luo et al. 2017), we find that all the sources lie within $\delta r/\sigma_r < 2.0$ (i.e. within the 95% confidence level), with only three, rather weak, sources (ID:698, ID:758 and ID:S-36) exceeding $\delta r/\sigma_r \approx 1.2$. These same three sources also have relatively large (~ 1 arcsec) counterpart-to-X-ray offsets in Luo et al. (2017). All 31 X-ray sources have clearly identified MIR counterparts, with a median FARMER model-based 5.6 μm magnitude of $m_{\text{F560W}} = 21.3 \pm 0.3$ with a 16th–84th percentile range of $m_{\text{F560W}} = 20.3 - 22.4$ and median 5.6 μm $S/N = 1199 \pm 264$. The full properties of the sample are presented in Table 1. In addition to the optical and infrared detections from HST and JWST respectively, 11 sources (35%) of the sample are detected in the far-infrared as part of the ALMA Spectroscopic Survey in the Hubble Ultra Deep Field (ASPECS; PI: F. Walter, Walter et al. 2016) as highlighted in Table 1. For a complete analysis of the ALMA-detected sources in the MIDIS survey see Boogaard et al. (2024).

4.2. Redshifts

There are spectroscopic redshifts for all 31 sources in our sample. For ninety per cent of them (28/31), spectroscopic redshifts are available from the far-infrared surveys (e.g. Boogaard et al. 2020, 2024) as well as near-infrared optical studies such as the MUSE HUDF Survey (Bacon et al. 2023). For the remaining three sources without published spectroscopic redshifts we utilise the public spectroscopic observations from FRESCO (Oesch et al. 2023) that target the MIDIS field. Following the same procedure as Boogaard et al. (2024), we extract spectroscopic redshifts for ID:797 at $z = 2.695$ and ID:805 at $z = 2.698$ based off the detected nebula line emission (e.g. $H\alpha$, [OIII]). For the remaining source, ID:695, which is not covered in the FRESCO Survey, we search the Next Generation Deep Extragalactic Exploratory Public (NGDEEP, PI: S. Finkelstein, #2079) Survey (Bagley et al. 2024). Again adopting the pro-

Notes. Column 1 lists the IDs adopted from Luo et al. (2017), where an ‘A’ indicates the source is detected in the ASPECS ALMA survey of the HUDF (Boogaard et al. 2024). Columns 2 and 3 indicate the X-ray-source coordinates, adjusted as described in Sect. 2. The updated spectroscopic redshifts of the sources are listed in column 4. The absorption-corrected intrinsic 0.5–7.0 keV luminosity, amended where necessary (from that reported by Luo et al. 2017) to reflect updated redshift, is given in column 5. The MIDIS 5.6 μm , SMILES 7.7 μm and MIDIS 10 μm integrated magnitudes are given in columns 6, 7 and 8. The class (AGN or Galaxy) is given in column 9 as defined in Luo et al. (2017) and F560W to X-ray offset is given in column 10. Objects classified as Galaxy in Luo et al. (2017) but as AGN in Lyu et al. (2022) or Lyu et al. (2024) are indicated with a † or ‡ respectively.

cedure of Boogaard et al. (2024), we identify a spectroscopic redshift of $z = 1.56$ for the X-ray source ID:694.

Our sample has a median redshift of $z = 1.22 \pm 0.19$ with a 16th–84th percentile range $z = 0.62$ –2.48. The redshifts of the

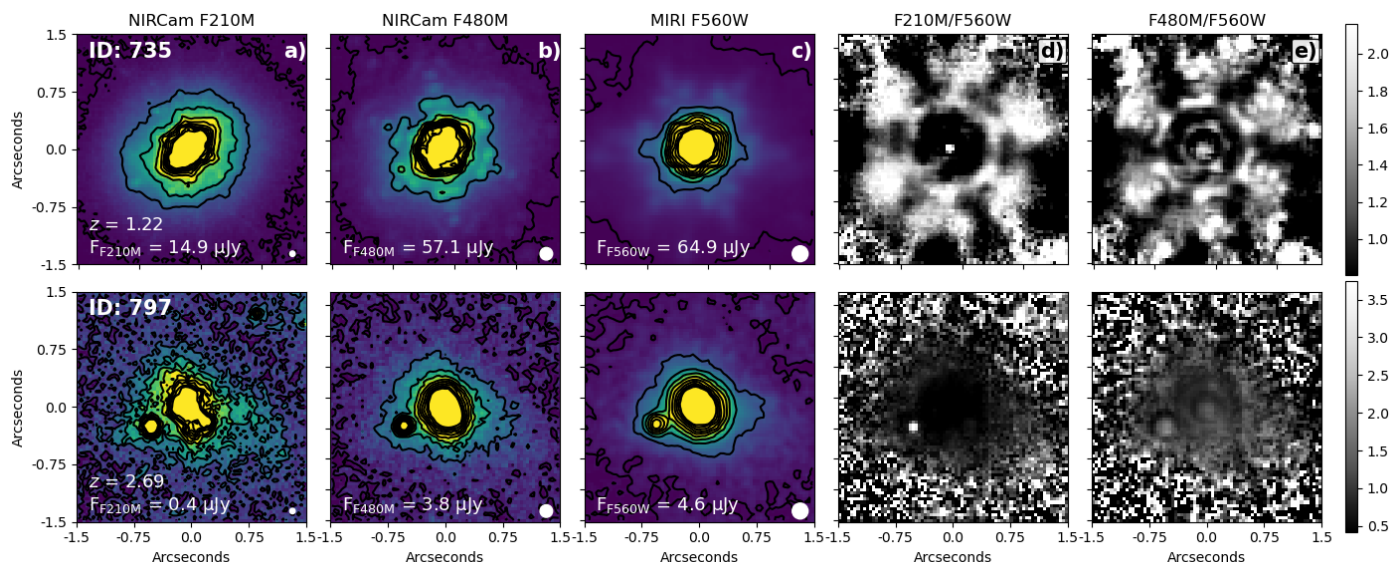

Fig. 3. JWST multi-wavelength imaging and colour maps for two examples of the X-ray sources in our sample. The full sample is shown in Appendix C. For each galaxy, we show, and contour, a 3-arcsecond cutout in the NIRCam F210M band (a), the NIRCam F480M band (b) and the MIRI F560W band (c). We label the galaxy’s ID as given by Luo et al. (2017), measured flux in each band and spectroscopic redshift. We also indicate the FWHM of the PSF in each band by the white circle in the lower-right corner. The F210M/F560W (d) and F480M/F560W (e) colour maps are shown for each source, highlighting the presence of any AGN (point source) component at longer (near-infrared) wavelengths.

full sample are presented in Table 1. For 12 sources we identify a different spectroscopic redshift to the photometric redshift used by Luo et al. (2017). We therefore update the redshift, and intrinsic X-ray luminosity, for the sources in our sample, with a median ratio of $L_{Xc}^{\text{MIDIS}}/L_{Xc}^{\text{L17}} = 1.04 \pm 0.05$. The updated X-ray luminosities, as well as spectroscopic redshifts, for the full sample are reported in Table 1 and in Figure 2 we plot the 0.5–7 keV absorption-corrected X-ray luminosity (L_{Xc}) for the 31 X-ray sources in the MIDIS survey as a function of their redshift, showing the comparison to the full sample presented in Luo et al. (2017).

4.3. Morphological Analysis

In Figure 1 we show the MIRI F560W/F770W/F1000W false colour images for the X-ray sources, highlighting the diverse range of morphology in the sample from compact, point-source red objects to extended, disc-like systems. These MIRI mid-infrared observations sample the galaxy emission at rest-frame $>1 \mu\text{m}$ providing insights into the structure and morphology of the continuum emission.

We visually assess the morphologies of the X-ray sources, in addition to both a non-parametric and parametric analysis of the MIRI F560W and F1000W observations, to quantify their rest-frame near-infrared morphology. We exclude the HST and NIRCam observations from our morphological analysis because we are interested in identifying the AGN component of the galaxies, which becomes more prominent at wavelengths greater than rest-frame $1 \mu\text{m}$. The analysis of the JWST imaging employs $5''0 \times 5''0$ cutouts of each source with pixel scales of $0''04$ per pixel⁷. The cutout in each filter is centred on the source detected in the MIDIS $5.6 \mu\text{m}$ observation. We use PHOTUTILS (Bradley et al. 2022) to model (and remove) the background level in each cutout as well as to quantify the root-mean-square (rms) noise. In the following sections “cutout” refers to these $10''0 \times 10''0$,

⁷ We use a slightly larger cutout than shown in Figure 1 and Figure 3 to ensure the background is well modelled.

background subtracted images that are used in the morphological analysis that follows.

Before measuring the galaxies’ morphology, we first define the point spread function (PSF) for each of the JWST bands. We adopt the PSFs used in Gillman et al. (in prep.) which were used to build THE FARMER catalogue. For the F560W band, this includes an empirical PSF made from stacked stars that accurately models the extended cross-form pattern of the F560W PSF, whilst for the MIRI F1000W band the PSF is generated from WEBBPSF (Perrin et al. 2014). For full details see Gillman et al. (in prep.).

4.3.1. Visual Morphology

To aid the visual classification we also generate two colour maps for each galaxy, an example of which is shown in Figure 3. The colour maps contrast the NIRCam F210M and F480M filters, which sample the rest-frame optical emission of the galaxies, with the MIRI F560W observation, which samples the rest-frame near-infrared emission. In this way, by contrasting the rest-frame optical and near-infrared emission any unresolved AGN-heated dust emission that begins to dominate over the stellar emission in the near-infrared clearly stands out (e.g. Martini et al. 2003). The colour maps of the full sample are shown in Appendix C.

The visual classification of all 31 target galaxies utilising the MIRI F560W and F1000W “cutouts” as well as corresponding colour maps was carried out by six team members (and co-authors). The initial classifications were assigned independently, and a final, merged outcome was produced from an interactive discussion. Where deemed necessary, a more detailed inspection was done with the F560W and F1000W images displayed using DS9⁸ and interactively optimising the greyscale or colour scale to view the faintest or brightest regions of an object.

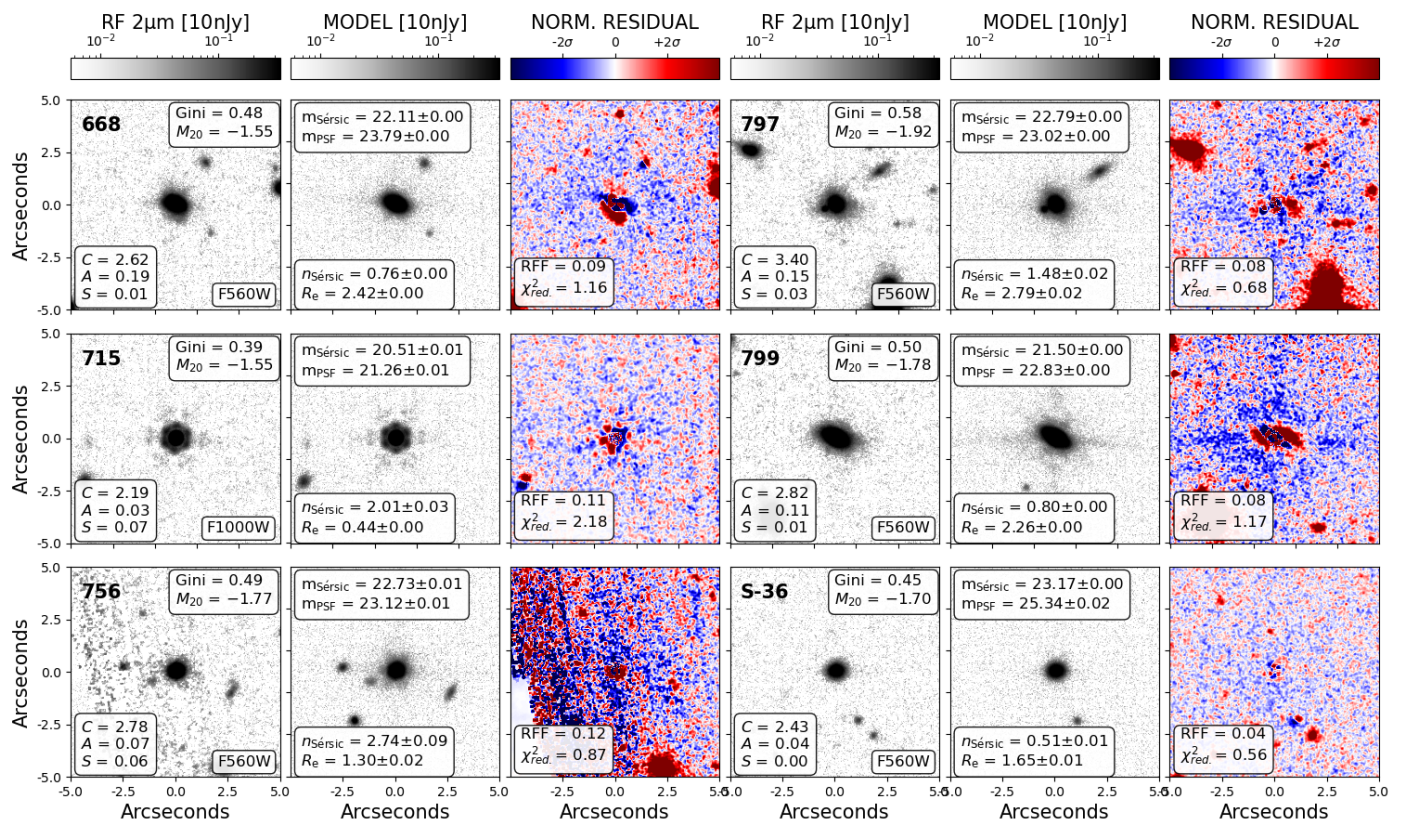

Fig. 4. Examples of the rest-frame $2\ \mu\text{m}$ morphological analysis for six X-ray sources in our sample, highlighting the diverse range of morphology in the sample. For each source, we show a 10-arcsecond cutout, best-fit Sérsic plus PSF parametric model and normalised residuals (residual/ σ). We label the source ID, MIRI filter, non-parametric (Gini, M_{20} , C , A , S) and parametric ($n_{\text{Sérsic}}$, R_e) morphological parameters, as well as goodness of fit parameters (χ_{red}^2 , RFF). For each parametric model we also annotate the Sérsic and PSF derived magnitude.

For ease of comparison with similar studies, we adopt the classification scheme used by Kartaltepe et al. (2023) in studying galaxy structure and morphology at $z = 3 - 9$ from the Cosmic Evolution Early Release Science (CEERS: PI: S.Finkelstein, #1345) programme. Hence we allow for recognition of up to four categories of surface-brightness morphology: *Disk*, *Spheroid*, *Irregular*, and *Point-source/Unresolved*. The first three are collectively referred to as *Extended*. Each galaxy can exhibit multiple extended-morphology classes. The main aim of this exercise is to identify the presence of: (i) point-source components, and (ii) extended emission components, for comparison with the morphological results from the parametric and non-parametric methods. We caution that there is some degree of subjectivity and uncertainty concerning the visual classification into the three individual extended-emission categories, as discussed in Kartaltepe et al. (2023), nevertheless, we consider that they form a useful basis for the cross-comparisons.

4.3.2. Non-Parametric Modelling

Next, we adopt a non-parametric approach to quantify the morphology of the X-ray-selected galaxies. This approach invokes no assumptions on the underlying structure of the galaxy’s light distribution, thus highlighting the unique properties of each source. Prior to quantifying the morphology we first smooth the source segmentation map generated from THE FARMER using the binary dilation routine in PHOTUTILS. Then, excluding this segmented region, we mask the remaining sources in the cutout, down to a 1σ isophote. This ensures full masking of any contam-

inants (spurious or otherwise). We run STATMORPH⁹ (Rodríguez-Gomez et al. 2019) on the masked cutouts in the $5.6\ \mu\text{m}$ and $10\ \mu\text{m}$ bands using the same segmentation maps and PSFs as for the THE FARMER catalogue (see Section 4.1).

STATMORPH measures the Concentration, Asymmetry and Clumpiness (C , A , S ; Abraham et al. 2003; Lotz et al. 2008) parameters that quantify how concentrated, asymmetrical and clumpy the galaxies’ surface brightness profiles are, with higher values indicating more concentrated, more asymmetrical, or clumpier light profiles respectively. In addition, the Gini and M_{20} parameters are also derived (for full definitions see Lotz et al. 2004; Snyder et al. 2015). Briefly, the Gini parameter defines the pixel distribution of the galaxy’s light, where $G = 1$ corresponds to all of the light concentrated in one pixel whilst $G = 0$ indicates each pixel contributes equally. The M_{20} parameter measures the second moment of the brightest 20 percent of pixels in the galaxy. This is normalised by the total moment for all pixels. Highly negative values indicate a high concentration of light, not necessarily at the centre of the galaxy.

4.3.3. Parametric Modelling

Finally, to quantify both the parametric morphological profiles of the galaxies and the deviations from these, we use the GALFITM code (Häußler et al. 2013). GALFITM is a Python-wrapper for GALFIT (Peng et al. 2010), that allows multi-component parametric models to be fit to a galaxy’s multi-wavelength light distribu-

⁹ <https://statmorph.readthedocs.io/en/latest/>

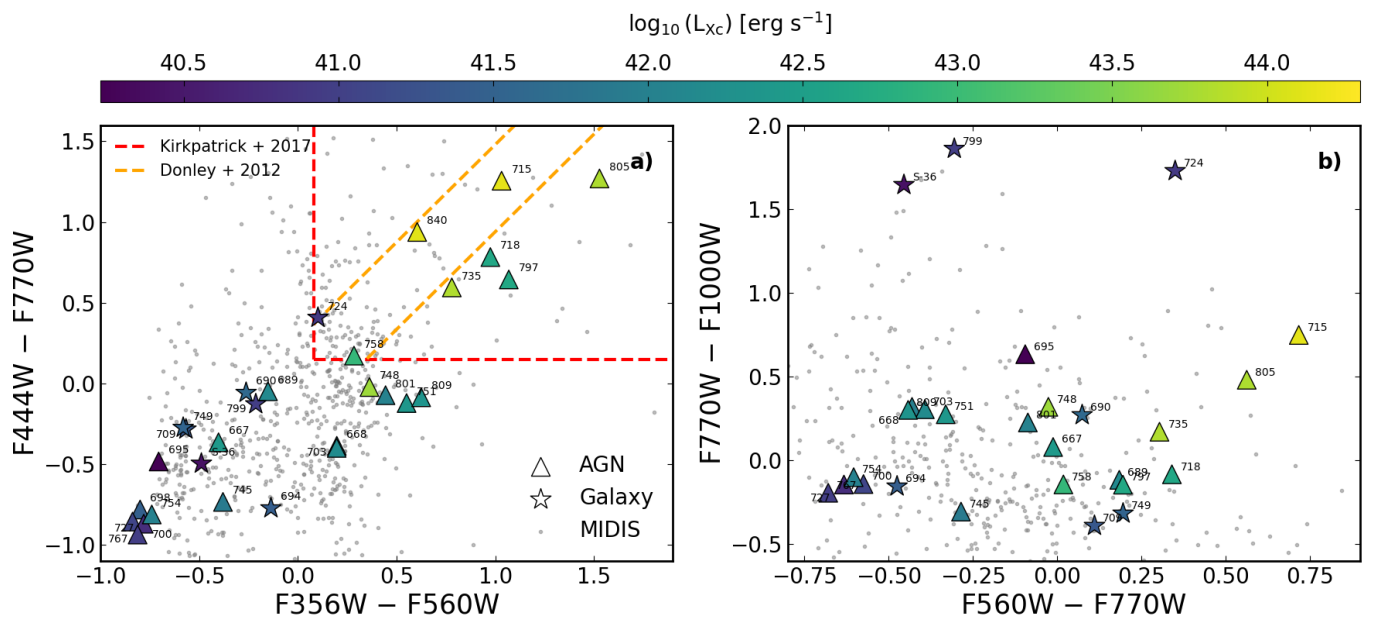

Fig. 5. The near-infrared colour properties of the 31 X-ray sources coloured by X-ray luminosity. Grey points are star-forming galaxies in the MIDIS field of view above $z > 0.5$. We show the $F444W - F770W$ colour versus $F356W - F560W$ colour (a), highlighting the near-infrared colour selected AGN region proposed by Kirkpatrick et al. (2017) (red-dashed line) and Donley et al. (2012) (orange-dashed line). In panel b) we plot the MIRI colours, $F770W - F1000W$ versus $F560W - F770W$. The three X-ray emitting galaxies with $F770W - F1000W > 1.5$, have a colour likely driven by the presence of the $6.2 \mu\text{m}$ PAH feature in the $F1000W$ filter with redshifts between $z = 0.46 - 0.67$ as demonstrated by Langeroodi & Hjorth (2023).

tion. For our analysis we fit each band independently thus allowing us to constrain the intrinsic wavelength dependence of each galaxy’s morphology. We further simultaneously model, with a single Sérsic model (Sérsic 1963), all sources within $3''0$ of the X-ray source, as identified in the THE FARMER segmentation map (see Section 4.1).

To model the target source, on which the cutout is centred, we fit two different models to each band to determine the presence of a point-source component to each galaxy’s light profile. First, we fit a single free Sérsic model with magnitude, Sérsic index (n), half-light radius, position angle and axis ratio free to vary. We then fit a free Sérsic model plus PSF model with the PSF model defined from the input PSF and parametrised with a position angle and magnitude. An example of the parametric modelling of the galaxies is shown in Figure 4.

To evaluate the goodness of fit of each of the models, we employ two metrics. First, we quantify the significance of the residuals to each model in each band using the residual flux fraction (RFF), as defined in Hoyos et al. (2011, 2012),

$$\text{RFF} = \frac{\sum_{i,j \in A} |I_{i,j} - I_{i,j}^{\text{model}}| - 0.8 \times \sum_{i,j \in A} \sigma_{\text{Bkg},i,j}}{\sum_{i,j \in A} I_{i,j}} \quad (1)$$

where the sum is performed over all pixels within 2.5 times the Kron radius as derived in the $F560W$ image. $|I_{i,j} - I_{i,j}^{\text{model}}|$ is the absolute value of pixel i, j ’s residuals to the model Sérsic fit, whilst $\sum_{i,j \in A} I_{i,j}$ indicates the total flux measured in the source as defined in Section 4.1. The 0.8 factor, multiplied by the sum over the background rms of the region ($\sigma_{\text{Bkg},i,j}$), ensures that a blank image with a constant variance has an $\text{RFF} = 0.0$ (see Hoyos et al. 2012 for details). Finally, we calculate the reduced

chi-squared of each model which is defined as:

$$\chi^2 = \sum_i^{N_d} r_i^2 \quad (2)$$

$$\chi_{\text{red.}}^2 = \chi^2 / (N_d - N_{\text{varys}}) \quad (3)$$

where $\sum_i^{N_d} r_i^2$ is the sum of the residual image, N_d is the number of data points and N_{varys} is the number of variable parameters. The model with the $\chi_{\text{red.}}^2$ close to unity is preferred.

4.4. Aperture photometry of point-source components

As an independent verification of the point-source fluxes derived from the GALFITM parametric modelling, which assumes the point-source component is well modelled by the PSF model, we perform aperture photometry on the target galaxies in the $F560W$ image and their free single Sérsic model residual images. We expect the GALFITM modelled point source fluxes to be larger than those derived from the residuals whilst being smaller than those derived from the input images that contain contributions from the host galaxy.

We use SEP (Barbary et al. 2016), a pythonic version of SOURCE EXTRACTOR (Bertin & Arnouts 1996a) to perform aperture photometry in $0''.2$ radius circular apertures centred on the MIRI source. We correct the aperture fluxes to “total” following the aperture corrections as reported by STScI¹⁰. For the residuals, on average, we find $\log_{10}(L_{\text{PSF}}^{\text{GALFIT}}) / \log_{10}(L_{\text{PSF}}^{\text{Aperture}}) = 1.04 \pm 0.01$. On the images themselves we derive a median value of $\log_{10}(L_{\text{PSF}}^{\text{GALFIT}}) / \log_{10}(L_{\text{PSF}}^{\text{Aperture}}) = 0.98 \pm 0.02$ highlighting the contributions from the host galaxy to the point-source emission.

¹⁰ <https://jwst-docs.stsci.edu/jwst-mid-infrared-instrument>

As a final validation of the point-source fluxes, we re-run the GALFIT modelling using the MIRI ePSF models from Libralato et al. (2024). We derive a field of view varying ePSF model following the same procedure as for the empirical PSF (see Boogaard et al. (2024) for full details). For the 31 X-ray sources we derive a lower point-source flux when using the ePSF models ($f_{\text{ePSF}}/f_{\text{empirical}} = 0.70 \pm 0.03$), which we suspect is driven by the lower noise level in the ePSF model and brighter cruciform pattern at large radii when compared to the empirical PSF. We note however the choice of PSF does not alter the results presented in the forthcoming sections.

5. Results and Discussion

From our sample of 31 X-ray detected galaxies, we have 24 AGN/AGN-candidates and 7 star-forming galaxies as classified from previous literature studies (e.g. Luo et al. 2017; Lyu et al. 2022, 2024) with a median redshift of $z = 1.22 \pm 0.19$ and a 16th – 84th percentile range $z = 0.62 - 2.48$. The AGN sources are identified through a multi-wavelength analysis that encompasses the objects’ X-ray, radio and infrared properties. One such selection is the mid-infrared colour selection, which isolates the potential AGN contribution to the near-infrared emission (e.g. Lyu et al. 2024).

In Figure 5a, we show the source integrated F444W – F770W versus F356W – F560W colour-colour diagram which mimics the IRAC colour selection commonly used to isolate AGN sources (Donley et al. 2012; Kirkpatrick et al. 2017), as indicated by the red and orange-dashed region. Whilst a small fraction (7/31) of the X-ray detected sources fall in the AGN parameter space, isolating the most luminous X-ray sources in our sample, the majority do not. It is well known that this colour selection is not robust against obscured or high-redshift AGN that can have near-infrared colours that mimic star-forming galaxies due to the dominance of stellar emission at these wavelengths in these systems (e.g. Cardamone et al. 2008; Donley et al. 2012; Mateos et al. 2015; Kirkpatrick et al. 2017; Lyu et al. 2022).

In Figure 5b, we show the MIRI F560W, F770W, F1000W colour-colour diagram, highlighting the comparable brightness across the three filters. In three of the X-ray sources classified as star-forming galaxies we identify excess F1000W emission compared to F770W with an $F770W - F1000W > 1.5$. These three galaxies (ID:724, ID:799 and ID:S-36) have redshifts between $z = 0.46 - 0.67$, making the F1000W filter sensitive to the 6.2 μm feature indicating the presence of star-formation activity. We suspect this drives their excess F1000W emission, as highlighted in Langeroodi & Hjorth (2023). This excess is not seen in the AGN at similar redshifts due to the presence of non-stellar emission dominating over the PAH features.

5.1. Visual Morphology

A summary of the visual classifications is given in Table 2, with a detailed breakdown of each source given in Appendix B. For a point-source component, we identify eight (6 AGN / 2 galaxy) objects where we consider it is likely present, 14 (11/3) where it is definitely present, and of these latter, ten (9/1) where the characteristic pattern of the instrumental PSF (Perrin et al. 2014) can be seen. For the nine cases where we do not report the presence of a point source, this should be taken as ‘absence of evidence’ rather than ‘evidence of absence’, as complexity and contrast in a galaxy’s emission morphology can limit the visual classification process. For extended emission, there are ten (8/2) objects where

Table 2. Visual classification statistics of the 31 X-ray emitting galaxies detected in the MIDIS survey.

Frequency	Likely Present		Interacting
	Present	Present	
Disc	6	7	
Spheroid	11	12	
Irregular	8	2	
Extended Sub-total	10	17	14
Point Source (Diff. pattern)	8	14 (10)	

Notes. Multiple extended-component categories may be present in a single object.

we consider it is likely present, and 17 (13/4) where it is definitely visible. There are 17 (12/5) objects with possible multiple extended component types, and 14 (11/3) where the morphology indicates a possible interacting system.

5.2. Morphological Modelling

To evaluate the presence of a point-source component by modelling the surface brightness profiles of the X-ray emitting galaxies, we assess the relative goodness of fit of parametric models using the reduced chi-squared and RFF parameters. For each galaxy we calculate a $\Delta\chi^2 = \chi^2_{\text{Sérsic}} - \chi^2_{\text{Sérsic+PSF}}$ and $\Delta\text{RFF} = \text{RFF}_{\text{Single}} / \text{RFF}_{\text{Single+PSF}}$. Defined in this way, a galaxy with $\Delta\chi^2 > 0$ and $\Delta\text{RFF} > 1$ indicates its morphology is better modelled with a single Sérsic plus PSF model.

On average, for the 31 galaxies in the F560W filter we identify an improved reduced chi-squared when fitting a Sérsic plus PSF model with a median value of $\chi^2_{\text{Sérsic}} - \chi^2_{\text{Sérsic+PSF}} = 3.35 \pm 1.12$ (see Appendix D). We further establish an average reduction in the amplitude of residuals for the two component model with $\Delta\text{RFF} = 1.28 \pm 0.08$. In two sources ID: 695 and ID: 709, we identify an increase in the residuals when fitting two components. Upon visual inspection (see Appendix B) the morphological measurements of both galaxies are clearly impacted by a companion, possibly merging, galaxy.

In Figure 6 we show the fractional point-source flux density in the F560W filter, $\text{ff}_{\text{PSF}}^{\text{F560W}}$, as a function of the Gini parameter ($\text{Gini}^{\text{F560W}}$), where ff_{PSF} is the point-source flux density relative to the total (Sérsic + PSF) flux density in the GALFITM model. The sources are coloured by the visual classification of point source presence (PSP) as defined in Sect. 4.3.1). We note there is overall, a positive correlation (as might be expected) between Gini and ff_{PSF} , albeit with a broad dispersion, indicating good agreement between the different morphological parameters. Those ‘AGN’ with visually no point source presence have a $\text{ff}_{\text{PSF}} \lesssim 0.2$, and similarly for the sources classified as ‘Galaxy’ with one exception ($\text{ff}_{\text{PSF}} \sim 0.55$). Conversely, it appears that point-source components with $\text{ff}_{\text{PSF}} \gtrsim 0.25$ can be reliably discerned by GALFITM. All sources with $\text{Gini} \gtrsim 0.5$ have the PSF pattern visible.

A recent study by Bonaventura et al. (2024), which analysed the near-infrared morphology of a sample of mid-infrared selected AGN, identified a 3- σ correlation between the observed-frame 1.5 μm asymmetry and the column density of the sources, establishing that mergers are more common amongst high-redshift obscured AGN. For the 24 AGN in our MIDIS sample of X-ray selected sources, we find no strong correlation between the 5.6 μm asymmetry and column density, with a median asymmetry of $A_{5.6 \mu\text{m}} = 0.06 \pm 0.02$, below the ‘mild’ disturbance threshold of $A = 0.1$ (see Bonaventura et al. 2024). We

Fig. 6. Example comparison of the three morphological analysis methods, for the MIRI/F560W waveband, for each source: Gini (STATMORPH) vs. fractional point-source flux density f_{PSF} (GALFITM), with the visual classifications of point-source presence indicated by colour-coding of each symbol (purple – no point-source identified; blue – likely; green – yes; yellow – yes, with a visible PSF characteristic diffraction pattern). The source classification, ‘AGN’ or ‘Galaxy’, is indicated by symbol shape: triangle and star respectively. The numbers by each symbol give the X-ray source reference (XID, Luo et al. 2017).

note that whilst we find no correlation between asymmetry and column density in our sample, this is not a direct comparison given the difference in rest-frame wavelength probed between the two studies. Furthermore, our sample is X-ray selected whilst the Bonaventura et al. (2024) AGN sample includes (X-ray undetected) infrared selected AGN which from previous HST studies, have been shown to exhibit a higher fraction of mergers (e.g. Kocevski et al. 2015; Donley et al. 2018; Ji et al. 2022).

5.3. Comparison with X-ray luminosity

Given the broad range of redshift of our sample from $z = 0.2 - 3.6$, the rest-frame wavelength probed by the MIDIS $5.6 \mu\text{m}$ ($10 \mu\text{m}$) observations varies from $4.7 \mu\text{m}$ ($8.3 \mu\text{m}$) to $1.2 \mu\text{m}$ ($2.1 \mu\text{m}$). To align the observations to a common rest-frame wavelength, we select the observation that samples closest to the rest-frame $2 \mu\text{m}$ emission. At $2 \mu\text{m}$ the emission is mostly unaffected by recent star-formation and highlights any AGN component if present. Given the redshift range detailed in Table 1, for 84% (26/31) of the sources we select the F560W filter, for 6% (2/31) we use the F1000W filter and for the remaining 10% (3/31) we use the F770W observations from the MIRI-SMILES survey as detailed in Section 3. In doing so, on average we sample the rest-frame $2.54 \pm 0.16 \mu\text{m}$, emission with a 16th–84th percentile range of $1.94 - 3.47 \mu\text{m}$.

To convert the point-source luminosity of the galaxies, as derived from GALFITM, to an intrinsic rest-frame luminosity we first convert the observed-frame fluxes to luminosities using the luminosity distance of each source. We then apply a K -correction of the form $(1+z)$ following the prescriptions of Hogg (1999) to derive the rest-frame $2 \mu\text{m}$ luminosity. Finally we scale the luminosities by the rest-frame frequency of the observations to

give final units of erg s^{-1} . In Figure 7a, we correlate the relative contribution of the point source component to the total $2 \mu\text{m}$ luminosity of each source, with the absorption-corrected intrinsic $0.5 - 7.0 \text{ keV}$ X-ray luminosity, identifying a correlation with a Spearman rank coefficient of $r_s = 0.48$. For 13/31 (42%) of the sources we find the relative point-source contribution to the total luminosity to be less than 20%. These sources exhibit no correlation with X-ray luminosity and represent the fainter X-ray sources in our sample with $\log_{10}(L_{\text{Xc}}) \leq 43 \text{ erg s}^{-1}$. For sources with a point-source contribution above 20%, we identify a stronger correlation with X-ray luminosity, but no dependence on the column density (N_{H}), which we adopt from Luo et al. (2017).

Of the galaxies in our sample, 5/7 (71%) have a point source to total luminosity ratio below 40%, with one galaxy (ID: 695) with the lowest X-ray luminosity in our sample ($\log_{10}(L_{\text{Xc}}) = 40.23 \text{ erg s}^{-1}$) having almost zero contribution from a point source in the mid-infrared ($< 0.01\%$), indicating the X-ray emission may arise from X-ray binaries or merger driven activity in the extended (non-nuclear) regions of the galaxy (e.g. Gao et al. 2003; Barrows et al. 2024). In contrast, two X-ray sources classified as galaxies (ID: 694 and ID: 690) have very high levels of point-source contribution, 79% and 57% respectively. Both of these galaxies are also visually classified as possibly undergoing interactions or mergers which makes the morphological modelling more uncertain. Furthermore both galaxies have small half-light radii ($R_{\text{h}} < 0''.26$), comparable to the PSF size of the MIRI observations, making it challenging to resolve the presence of a host galaxy, with both sources remaining point-source like even at rest-frame optical wavelengths ($\lambda < 0.4 \mu\text{m}$). As noted by Luo et al. (2017), some of the X-ray sources classified as galaxies in their analysis might host low-luminosity or heavily obscured AGN that remain undetected based on the six selection criteria used for AGN identification (see Luo et al. (2017) for full details.). Looking at the spectral properties of ID: 694 and ID: 690 from the NGDEEP prism spectra (see Section 4) there is no clear evidence of AGN activity i.e broad-line emission.

In Figure 7b we correlate the $2 \mu\text{m}$ point-source luminosity of the sources with their X-ray luminosity. We exclude sources with point-source to total fraction of less than 20% (13 sources) which showed no correlation with X-ray luminosity as identified in Figure 7a. We identify a strong correlation with a Spearman rank coefficient of $r_s = 0.73$, although no strong dependence on the column density as derived by Luo et al. (2017). We derive a running median in bins of 1 dex in X-ray luminosity, as shown by the grey squares in Figure 7b, which we quantify further using a linear orthogonal distance regression (ODR) fit of the form,

$$\log_{10}(L_{2 \mu\text{m,PS}}^{\text{GalFit}}) = \alpha \log_{10}(L_{\text{Xc}}) + \beta \quad (4)$$

establishing $\alpha = 0.55 \pm 0.04$ and $\beta = 20.10 \pm 1.70$.

We compare our relation between near-infrared point-source luminosity and X-ray luminosity to other literature samples of Quasars and AGN. Specifically we plot the sample of local ($z \sim 0.01$) Seyfert 1 (blue triangles) and 2 (red triangles) AGN from Burtscher et al. (2015). We convert the $2 - 10 \text{ keV}$ X-ray luminosities reported in Burtscher et al. (2015), to the $0.5 - 7 \text{ keV}$ energy band using a scaling factor of 0.73 derived from WEBPIMMS¹¹, assuming a (negative) power-law spectrum with photon index of 1.8 and (galactic) column density absorption of

¹¹ <https://heasarc.gsfc.nasa.gov/cgi-bin/Tools/w3pimms/w3pimms.pl>

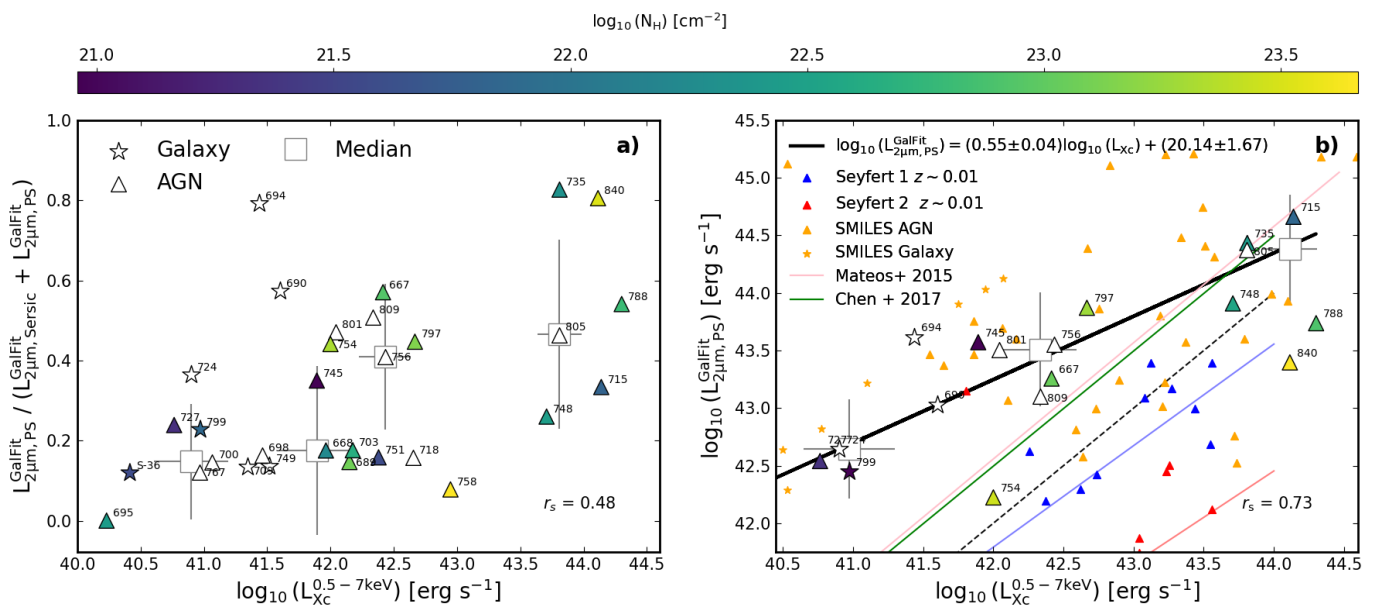

Fig. 7. We show the relation between the ratio of rest-frame 2 μm point source (PS) luminosity to total (PSF + Sérsic) 2 μm luminosity (*a*) and PS luminosity (*b*) as a function of the 0.5–7.0 keV X-ray luminosity. In each panel we show the Spearman rank correlation coefficient (r_s) for the relations, a running median (grey squares) in bins of 1 dex in X-ray luminosity. We exclude sources in panel *b*) with a PS to total luminosity ratio of less than 20%. We further show the one-to-one relation (black-dashed line) and overlay nearby ($z \sim 0.01$) AGN from Burtscher et al. (2015), as well as the 6 μm –X-ray luminosity relations from Mateos et al. (2015) for $z \approx 0.2$ –2.8 AGN and higher redshift Quasars from Chen et al. (2017), as well as the MIRI-SMILES X-ray sources from Lyu et al. (2024). Whilst we identify a strong ($r = 0.73$) correlation between near-infrared point-source luminosity and X-ray luminosity in our samples, at $\log_{10}(L_{Xc}) \leq 43 \text{ erg s}^{-1}$, we identify higher 2 μm PS luminosities than other studies, with no strong correlation with column density (N_H).

$N_H = 9 \times 10^{19} \text{ cm}^{-2}$ following Luo et al. 2017.¹² We note the near-infrared luminosity reported in Burtscher et al. (2015) is derived from a combination of the radial CO equivalent-width profile and spectral decomposition, and might thus not be directly comparable to our morphological decomposition.

In addition to the local AGN, we compare to the relations derived by Mateos et al. (2015) and Chen et al. (2017), for X-ray AGN and Quasars across a broad range of redshift ($z \approx 0.2$ –2.8). Both these studies report the relation between the galaxy integrated rest-frame mid-infrared (6 μm) and 2–10 keV X-ray luminosity, which we convert to the 0.5–7 keV energy band using the same scaling as for the Burtscher et al. (2015) sample. We further include the comparison to the recent study by Lyu et al. (2024) of the 217 AGN reported in the MIRI SMILES survey in GOODS-S. In Figure 7b we plot the X-ray detected MIRI-SMILES AGN (orange triangles) and Galaxies (orange stars), again converting to the 0.5–7 keV energy band. All three of these samples are derived at longer rest-frame wavelengths than 2 μm . In the absence of strong star-formation activity, at 6 μm for a power-law spectrum any AGN component of the X-ray source will dominate over the stellar emission of the host galaxy, removing the need for any decomposition of fluxes at this wavelength. Thus we expect the rest-frame 6 μm luminosity to be larger than the 2 μm luminosity in our sample.

In Figure 7b we see that, whilst the high X-ray luminosity ($\log_{10}(L_X) \geq 43.5 \text{ erg s}^{-1}$) MIDIS sources are consistent with other studies, the lower luminosity sources are offset to higher near-infrared luminosities, compared to all pre-JWST surveys. However the low X-ray luminosity MIDIS sources are comparable to the 6 μm –X-ray luminosity relation identified in the MIRI-SMILES survey, with near-infrared luminosities more

than an order of magnitude higher than expected from the Burtscher et al. (2015) sample. Whilst the low X-ray luminosity MIDIS sources align with the MIRI-SMILES galaxies and AGN from Lyu et al. (2024), as noted before this is not a direct comparison to the SMILES sample due to the offset in rest-frame wavelength probed by the infrared observations.

To understand the origin of this offset we investigate a number of different scenarios for the X-ray sources classified as galaxies and AGN. Firstly, the origin of the near-infrared point-source emission might come from nuclear starburst activity. For instance, known local nuclear starbursts such as Arp 220, with an X-ray luminosity of $\approx 10^{40} \text{ erg s}^{-1}$ has a rest-frame 2.2 μm point-source luminosity of $\approx 10^{43} \text{ erg s}^{-1}$ (e.g. Scoville et al. 2000; Iwasawa et al. 2011). Of the three most offset sources in this regime, two (ID: 799 and ID: 724) are classified as galaxies, indicating the AGN contribution is minimal or currently undetected. As also highlighted in Figure 5, these two X-ray sources have redshifts of $z \sim 0.6$, thus placing the 3.3 μm PAH feature in the F560W filter. Hence this may result in an excess in this filter thus boosting the near-infrared luminosity in the presence of strong star-formation activity (e.g. Langeroodi & Hjorth 2023). Furthermore, ID: 724 has a reported 1-mm flux of $S_{1.2\text{mm}} = 34 \pm 10 \mu\text{Jy}$ from the ASPECS survey (Aravena et al. 2020; Boogaard et al. 2024), further indicating the presence of intense star-formation activity. Both ID:799 and the AGN with the largest offset (ID:727) have featureless NGDEEP prism spectra (see Section 4), with no clear signs of AGN activity. Meanwhile ID:724, has a clear detection of a broad Pa β line, potentially indicating the presence of AGN activity in this source previously classified as a galaxy. We note however it is difficult to definitively determine the presence of AGN activity in the prism spectrum given the low ($\sim 2000 \text{ km s}^{-1}$) resolution.

¹² For an index of 1.4, the conversion factor would be ≈ 1.0 .

Another possible reason for the large offset at low X-ray luminosities, might be that the intrinsic X-ray luminosity of these sources could be underestimated if their column density is underestimated. We can calculate the increase in column density required for the least luminous X-ray sources, with $\log_{10}(L_{Xc}) \sim 41.0 \text{ erg s}^{-1}$, to be consistent with the Burtcher et al. (2015) sample. For example, the AGN source ID: 727 has a power-law index of $\gamma = 1.65$ and a column density of $N_H = 2.1 \times 10^{21} \text{ cm}^{-2}$ as reported by Luo et al. (2017). Using `WEBPIMMS`, we estimate that a column density of $N_H \sim 3 \times 10^{24} \text{ cm}^{-2}$ would be needed to yield the required absorption factor ~ 30 to be applied to the observed X-ray luminosity. We note that this scenario may not be physically reasonable, given that the source has a significant detection in the Chandra ‘soft’ band (0.5–2 keV; Luo et al. 2017). However, in the next luminosity bin at $\log_{10}(L_{Xc}) \sim 42.04 \text{ erg s}^{-1}$ the required column density to enhance the intrinsic X-ray luminosity is not so extreme, with the uncertainty on the median bin making it nearly consistent with the relations from Mateos et al. (2015) and Chen et al. (2017).

We note that the excess identified at low X-ray luminosity is unlikely to be driven by just one of these scenarios, and is more likely a relative combination of all processes that is driven by the unique evolutionary path of each galaxy. This study of the X-ray sources within the MIDIS observations has demonstrated the power of deep, high resolution mid-infrared imaging with MIRI whilst highlighting the complex nature of X-ray sources in the distant Universe and the need for the upcoming MIDIS-Red observations at 7.7 μm and 10 μm with equivalent 5σ point source depth, that will unveil the true nature of X-ray sources and AGN in the HUDF.

6. Conclusions

The unprecedented mid-IR sensitivity and imaging resolution of MIRI, and the great depth of the MIDIS survey, allow, in many cases, the direct characterisation of point-like (i.e. unresolved) components in high-redshift galaxy images, at rest-frame near-infrared wavelengths.

- Our sample consists of the 31 X-ray sources (CDF-S, Luo et al. 2017) in the MIRI Deep Imaging Survey (MIDIS) of the HUDF, using two filters F560W and F1000W.
- From the measured mid-infrared emission, the sources classified as ‘Galaxy’ do not appear to have clearly distinct properties, though we note that three of them show high colour values F770W – F1000W, likely driven by the presence of the 6.2 μm PAH feature in the F1000W filter with redshifts between $z = 0.46 - 0.67$ (Fig. 5b).
- We employ three methods to examine the presence of rest-frame mid-infrared unresolved emission, which is assumed to arise in AGN-heated hot dust. Two are based on morphological modelling techniques (parametric and non-parametric), and one on visual inspection. There is broad agreement between these methods (Fig. 6).
- At least 70% of the sources show unresolved emission in the MIRI images, with the unresolved-to-total flux fraction ranging from ~ 0.2 to ~ 0.9 . About half of our sample have published X-ray column densities (Luo et al. 2017). We find no strong correlation between the column densities and the ratio of the point-source component to the total 2-micron rest-frame luminosity. For an obscured AGN having a high column density, we might have expected a smaller point-source contribution.

- In common with previous studies we confirm a strong correlation between the 2-micron (rest-frame) point-source luminosity and the X-ray luminosity, with a Spearman rank coefficient of $r_s = 0.73$ (Fig. 7). We establish a shallower slope than previous studies with $\alpha = 0.55 \pm 0.04$, giving rise to an excess rest-frame near-infrared 2 μm luminosity below $\log_{10}(L_{Xc}) = 43.5 \text{ erg s}^{-1}$, comparable to that derived by Lyu et al. (2024) at 6 μm .
- We speculate this offset to be driven by a combination of compact galaxy size, nuclear starburst activity, Compton-thick AGN and 3.3 μm PAH emission acting to enhance the near-infrared point source emission.

The current MIDIS data will be augmented during 2024–2025 by deep imaging at longer wavelengths (F770W and F1000W) with programme id. 6511, PI G. Östlin, facilitating identification of obscured AGN at redshifts $\sim 3-4$.

Notes. Column 1 lists the IDs adopted from Luo et al. (2017), where an ‘A’ indicates the source is detected in the ASPECS ALMA survey of the HUDF (Boogaard et al. 2024). Columns 2 and 3 indicate the rest-frame 2 μm luminosities for the PSF and Sérsic model, converted to units of erg s^{-1} using the rest-frame frequency, whilst column 4 details the PSF to total luminosity fraction of the source from the GALFIT modelling. The Sérsic index, effective radius, Gini and M_{20} parameters are given in columns 5, 6, 7 and 8. In columns 9 and 10 we list the visual classification of extended and point-source components, for ease of comparison with the quantitative results (see Appendix B for details).

Appendix B: Visual classification: details**Table B.1.** Visual classification for each object in our sample, ordered by X-ray ID from Luo et al. (2017).

ID	Class	Class_ref	Morphological categories identified in each object					Notes
			Disk	Spheroid	Irregular	Extended	Point_Source [c]	
667	AGN	Luo17		likely		likely	yes: psf	
668	AGN	Lyu22	likely	yes		yes		00923 [a]
689	AGN	Luo17	yes		likely	yes		interacting?
690	Galaxy	Luo17	likely	yes	likely	yes		interacting?
694	Galaxy	Luo17		likely		likely	yes	interacting?
695	AGN	Lyu22	likely		likely	likely		interacting?
698	AGN	Lyu22		yes		yes		
700	AGN	Lyu22		yes		yes	yes: psf	
703	AGN	Lyu22	yes	yes		yes	likely	01520 [a]
709	Galaxy	Luo17	likely	likely	likely	likely	likely	interacting?; East IR source is X-ray source
715	AGN	Luo17					yes: psf	
718	AGN	Luo17		likely	likely	likely		interacting?
724	Galaxy	Luo17					yes: psf	
727	AGN	Lyu22	likely	likely		likely	yes: psf	
735	AGN	Luo17					yes: psf	
745	AGN	Luo17		likely		likely	yes: psf	
748	AGN	Luo17	yes	likely		yes	yes: psf	
749	Galaxy	Luo17	yes	likely		yes	yes	
751	AGN	Lyu24			yes	yes		interacting?; 00272 [a]; complex morphology
754	AGN	Luo17	yes	yes		yes	likely	interacting?
756	AGN	Lyu22		yes		yes	likely	
758	AGN	Luo17			yes	yes		interacting?
767	AGN	Lyu22	likely	yes		yes	likely	
788	AGN	Luo17		likely	likely	likely	yes	interacting?; [b]
797	AGN	Luo17		yes		yes	yes	interacting?
799	Galaxy	Luo17	yes	yes		yes		
801	AGN	Lyu22		yes	likely	yes	likely	interacting?
805	AGN	Luo17					yes: psf	interacting?
809	AGN	Luo17		likely	likely	likely	likely	interacting?
840	AGN	Luo17		likely		likely	yes: psf	
S-36	Galaxy	Luo17	yes	yes		yes	likely	00862 [a]

Notes.

a. NGDEEP_nnnnn (Shen+24 H-alpha map)

b. also in $z > 3$ massive galaxies sample (CANDELS 14587; Costantin+24)

c. yes: psf – indicates PSF characteristic diffraction pattern is visible

Appendix C: Colour Maps

Fig. C.1. Multi-wavelength imaging and colour maps for all 31 X-ray sources in our sample. For each galaxy, we show, and contour, a 3-arcsecond cutout in the NIRCam F210M band (a), NIRCam F480M band (b) and the MIRI F560W band (c). For each cutout, we label the galaxy’s ID as given by Luo et al. (2017), measured flux in each band and spectroscopic redshift. We also indicate the FWHM of the PSF in each band by the white circle in the lower-right corner. The F210M/F560W (d) and F480M/F560W (e) colour maps are shown for each source, highlighting the presence of any AGN (point source) component at longer (near-infrared) wavelengths.

Appendix D: Morphology Statistics

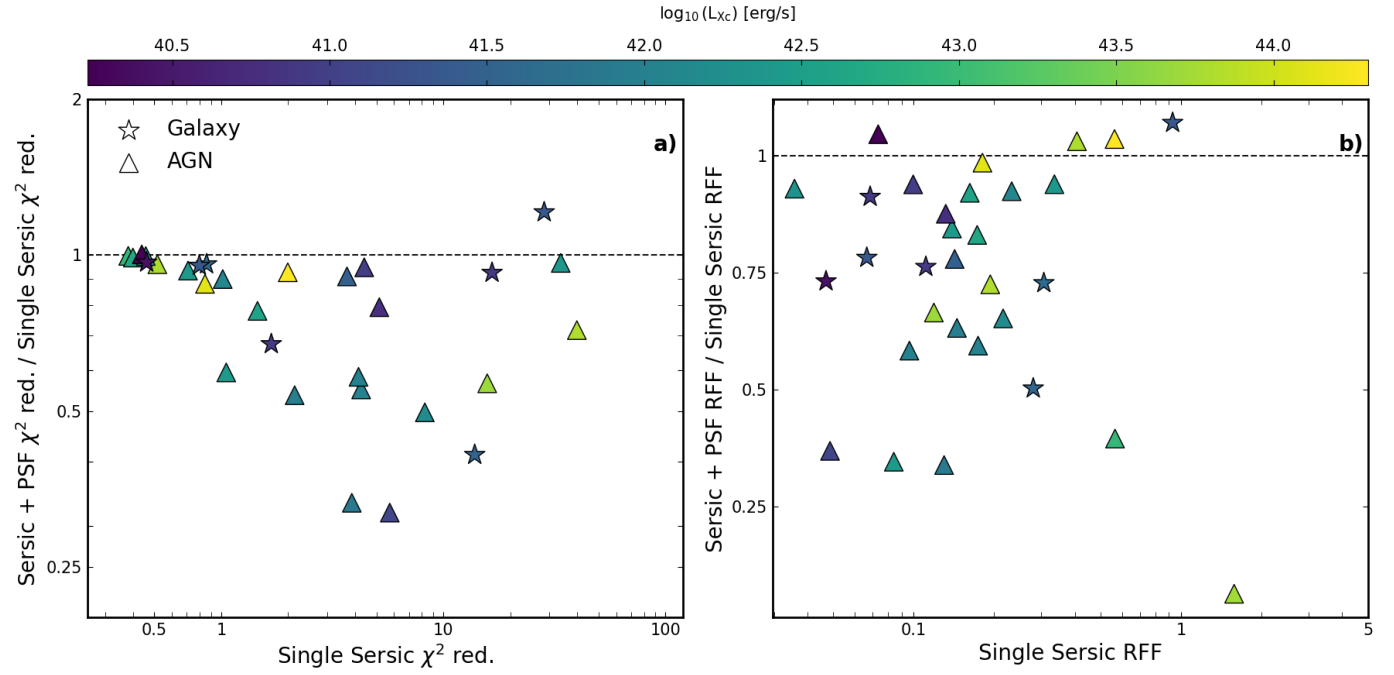

Fig. D.1. The *GALFIT* modelling statistics for the 31 X-ray sources at rest-frame 2 μm . We compare the single Sérsic fit to a Sérsic plus PSF model, analysing the difference in reduced chi-squared (*a*), and RFF (*b*). For the majority of sources, we identify improved reduced chi-squared and RFF values between the two models.
