James Webb Space Telescope (JWST) has uncovered a new population of compact objects that show a unique V-shaped spectral energy distribution (SED) in the UV and optical wavelength range. These so-called “little red dots” (LRDs) often exhibit broad Balmer emission lines, indicative of the presence of active galactic nuclei (AGNs). They generally lack detection of X-ray, radio, and mid-IR radiation, which is fundamentally different from typical AGNs. Various models, including super-Eddington-accreting black holes enshrouded in dense and dust-poor gas, have been proposed to explain these features. However, the nature of LRDs remains debated, and their evolutionary fate is unclear. Here we report two unusual LRDs at redshift $z = 2.868$ and 2.925 that are in a transitional phase towards typical AGNs. Their V-shaped SEDs, compact optical morphology, and broad emission lines satisfy the defining criteria of LRDs. On the other hand, they exhibit intense X-ray, radio, and mid-IR radiation that is much stronger than previously known LRDs. These hybrid properties suggest that the dense gas envelope around their central black holes is dispersing, allowing high-energy photons and radio emission to escape. Meanwhile, a dust torus is forming. This finding provides a direct insight into the nature of LRDs and indicates that at least some LRDs will evolve into AGNs or quasars at later times.

LRDs are characterized by their distinctive V-shaped SED that consists of a red optical continuum and a blue UV continuum^{1,2} with a turnover point consistently located near the Balmer limit³. They have point-like rest-frame optical morphology with a typical effective radius $R_e \sim 100$ pc^{4,5} or less^{1,6}, and more than 70% of them show broad Balmer emission lines^{2,7,8}. These observational features provide strong evidence for the presence of accreting supermassive black holes (SMBHs). However, some key observational signatures of typical AGNs are weak or absent from LRDs, including X-ray emission from hot corona^{9,10}, mid-IR emission from hot dust^{11,12}, and radio emission¹³. In addition, Balmer absorption is observed in a large fraction ($\geq 20\%$) of LRD spectra^{14,15}, supporting a scenario in which a super-Eddington SMBH is enshrouded by very dense gas^{16,17,18}. Although most LRDs do not show significant UV–optical variability^{19,20}, a small fraction of them display variability that is consistent with actively accreting BHs^{6,20,21,22}. While the physical mechanism underlying their characteristic properties remains poorly understood, little is known about their evolutionary pathway as well. The LRD occurrence rate follows a log-normal distribution that peaks at $z \sim 6$ and declines sharply towards lower redshifts^{4,23,24}, so LRDs may represent an early and short-lived phase of SMBH growth²⁵. The rapid decline toward later times indicates that LRDs do not persist as a distinct population. It is unclear whether LRDs evolve into typical AGNs, and if so, how this transition occurs.

In this work, we present two unique LRDs at $z = 2.868$ and 2.925 . They show strong emission in

the X-ray, radio, and mid-IR bands, offering a deep insight into the evolutionary path of LRDs. We hereafter refer to these two objects as *Forge I* and *Forge II*. The *Forges* were found in the COSMOS field using the combination of JWST NIRCcam (F090W, F115W, F200W, F277W, F356W, and F444W), HST (F814W), Subaru (*grizy*), and CFHT (*U*) images (Methods). They are unresolved in the JWST NIRCcam F444W images, and their F444W magnitudes are 20.03 and 19.25 mag (magnitudes are in the AB system), respectively. They have blue UV slopes ($\beta_{\text{UV}} = -1.23$ and -0.73) and red optical slopes ($\beta_{\text{opt}} = 2.91$ and 1.44) in the rest frame that satisfy the widely adopted LRD V-shaped SED criterion⁴ ($\beta_{\text{UV}} < -0.37$ and $\beta_{\text{opt}} > 0$). The *Forges* were also observed with JWST NIRCcam F444W slitless spectroscopy. The spectra display broad emission lines of He I $\lambda 10830$ (hereafter He I), Pa γ , and O I $\lambda 11287$ as well as He I and Pa δ absorption lines that are frequently seen in the JWST spectra of LRDs^{26,27,28}. Figure 1 shows the broadband SEDs and images of the *Forges*, Figure 2 shows the spectra, and Table 1 lists the basic source information, photometry measurements and derived properties. We adopt a standard Λ CDM cosmology with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$, where H_0 is the current value of the Hubble constant, and Ω_m and Ω_Λ are the cosmological density parameters for matter and dark energy, respectively.

We estimate the central BH masses M_{BH} and bolometric luminosities L_{bol} of the *Forges* using the spectral and photometric data above. We first model their continuum and line emission and absorption features in the JWST slitless spectra (Methods), and the best-fit results are listed in Extended Data Table 1. The full widths at half maximum (FWHM) of the emission lines are about several thousand km s^{-1} , confirming their AGN nature. In addition, the strong O I $\lambda 11287$ emission agrees with the predicted signature of high-accretion SMBHs²⁹. Assuming that these lines originate from the AGN broad-line regions, we calculate BH mass using the broad Paschen emission lines and the $1 \mu\text{m}$ continuum luminosity³⁰. The resultant masses are $(3.72 \pm 1.86) \times 10^8 M_\odot$ and $(9.78 \pm 4.89) \times 10^8 M_\odot$ (M_\odot is the Solar mass), respectively. *Forge II* was also observed by the DESI spectroscopic survey and HST G141 slitless spectroscopy. Only narrow Ly α emission line (FWHM= 556 km s^{-1}) is detected by DESI, shown in the lower panel of Figure 2. Canonical AGN broad lines, including Ly α , N V $\lambda 1240$, C IV $\lambda 1549$, He II $\lambda 1640$, and C III] $\lambda 1909$, are not detected, which is consistent with previous results that high-redshift LRDs have weak or no broad UV emission lines^{7,28}. We assume that the central AGNs are obscured in the rest-frame UV, but dominate in the near-IR, radio, and X-ray bands, then we obtain AGN bolometric luminosities L_{bol} by integrating their reprocessed SEDs (Extended Data Figure 3). The inferred Eddington ratios are $L_{\text{bol}}/L_{\text{Edd}} = 0.17^{+0.25}_{-0.08}$ and $0.24^{+0.42}_{-0.12}$, where the Eddington luminosity is $L_{\text{Edd}} = 1.3 \times 10^{38} (M_{\text{BH}}/M_\odot) \text{ erg s}^{-1}$.

We also detect strong and slightly redshifted He I absorption lines in the spectra of the two objects. The absorption indicates inflows or fallback³¹ that is different from commonly seen blueshifted troughs explained by AGN-driven outflows. Meanwhile, *Forge II* has a blueshifted Pa δ absorption line that corresponds to an outflow velocity of 317.5 km s^{-1} , implying complex gas kinematics. Such Pa δ absorption, like Balmer absorption, arises in dense and excited gas due to the short-lived populations of the $n = 2$ or $n = 3$ levels, and is much rarer than He I absorption that has also been observed in some pre-JWST AGNs^{31,32}. Therefore, the detection of the Pa δ absorption further suggests the presence of high-density, low-ionization gas surrounding the *Forges*.

While the lack of UV emission lines and the strong He I absorption make *Forges* closely resemble LRDs, their X-ray detection reveals that they diverge in the level of obscuration and/or accretion activity. The *Forges* have X-ray observations by the XMM-Newton Wide-Field Survey³³ and the Chandra COSMOS Legacy Survey³⁴. Both sources are X-ray luminous, with observed 2–10 keV X-ray luminosity $L_X = 2.6 \times 10^{44} \text{ erg s}^{-1}$ and $8.9 \times 10^{44} \text{ erg s}^{-1}$, respectively (Methods). The best-fit gas column densities

(N_{H}) are $2.1_{-1.3}^{+1.8} \times 10^{22} \text{ cm}^{-2}$ and $1.4_{-1.3}^{+1.8} \times 10^{22} \text{ cm}^{-2}$. The modest X-ray obscuration, along with the non-detection of broad UV lines, indicates that the *Forges* are different from heavily obscured AGNs. Their bolometric-to-X-ray luminosity ratios, $L_{\text{bol}}/L_{\text{X}} \simeq 43$ and $\simeq 51$, are smaller than those of most high-redshift LRDs²¹. For *Forge II*, we also detect the 6.4 keV Fe $K\alpha$ line with a confidence level of 98.4% ($p = 0.016$) (Extended Data Figure 4), which is a characteristic X-ray feature of AGNs. Both sources exhibit strong X-ray variability (Extended Data Figure 5). The L_{X} variability of *Forge I* reaches a maximum amplitude of $5.4_{-2.7}^{+37.8}$ (defined as the ratio of the maximum to minimum flux) over a timescale of ~ 2 years in the observed frame. *Forge II* shows a variability amplitude of $1.7_{-1.0}^{+0.8}$ over ~ 0.5 years. In both cases, the observed variability exceeds what is typically seen in AGNs³⁵. In contrast to their X-ray variability, they show no apparent variability in the F115W-band images over a baseline of two years. These behaviors are consistent with the prediction for high-accretion LRDs, where photon trapping suppresses UV variability while allowing strong X-ray fluctuations²¹. Our following analysis indicates that the measured UV flux is dominated by extended emission rather than by the central AGNs (Extended Data Figure 1 and 2), which further dilutes the variability amplitude. The observed UV-to-X-ray power-law spectral slope $\alpha_{\text{ox}} = f_{2 \text{ keV}}/f_{2500 \text{ \AA}}$ largely deviates from the $\alpha_{\text{ox}} - L_{2500 \text{ \AA}}$ relation for AGNs, where $f_{2500 \text{ \AA}}$ is the measured rest-frame 2500 \AA flux dominated by the host galaxy. Using the intrinsic $f_{2500 \text{ \AA}}$ inferred from the ionized nebular emission (see below and Extended Data Figure 6), the corrected α_{ox} agrees with the observed X-ray luminosity (Extended Data Figure 7). These results imply that the intrinsic UV radiation is generally consistent with normal AGNs.

The *Forges* also exhibit radio emission, a property commonly seen in normal AGNs. They are both detected by the VLA-COSMOS deep 3 GHz survey³⁶, with flux densities of $15.2 \pm 2.4 \mu\text{Jy}$ and $83.9 \pm 4.8 \mu\text{Jy}$, respectively. Furthermore, *Forge II* is detected by the VLA-COSMOS Large Project³⁷ with a flux density of $183 \pm 25 \mu\text{Jy}$ at 1.4 GHz. The derived radio spectral index is $\alpha = -1.02 \pm 0.19$ (where $f_{\nu} \propto \nu^{\alpha}$), consistent with the distribution of spectral indices ($\alpha = -0.73 \pm 0.35$) in large radio AGN samples³⁶. Adopting this spectral index for both sources yields observed or apparent radio-loudness parameters of $R = 28.3$ and 48.5 , where R is defined as $R = f_{5\text{GHz}}/f_{4400 \text{ \AA}}$ and $f_{4400 \text{ \AA}}$ is the rest-frame 4400 \AA flux derived from the F115W- and F200W-band flux. Using the intrinsic $f_{4400 \text{ \AA}}$ inferred from the ionized nebular model below (Extended Data Figure 6), the radio loudness values decrease to $R = 5.2$ and 1.5 that are both below the conventional threshold for radio-loud AGNs ($R > 10$). We further find that the *Forges* are broadly consistent with radio-quiet AGNs³⁸ in the fundamental plane (Extended Data Figure 7). This suggests that their X-ray and radio emission may already reach the level of normal AGNs, but the UV emission is still largely suppressed.

We perform multi-band image decomposition to understand the different components of the *Forges* (Methods). Similar to other LRDs, the *Forges* become increasingly point-source dominated from $\lambda_{\text{obs}} \sim 2 \mu\text{m}$ ($\lambda_{\text{rest}} \sim 5000 \text{ \AA}$) toward longer wavelengths, while appearing extended at shorter wavelengths in the JWST images. Our initial decomposition procedure uses a model with one point spread function (PSF) and one Sérsic component, and reveals significant off-center residuals that are particularly strong in the F200W and F277W bands. These two bands cover [O III]+ $\text{H}\beta$ and $\text{H}\alpha$, respectively. Therefore, we add an additional Sérsic profile to represent the off-center component in the model, and we attribute this component as nebular emission rather than stellar emission³⁹, as supported by its morphology and large line equivalent width (EW). Extended Data Figures 1 and 2 and Extended Data Table 2 present our image decomposition results. These results disclose an emergence of point-source emission that is weak in the UV but dominates the optical to near-IR radiation. This is consistent with the non-detection of high-ionization UV emission lines from AGNs.

With the image decomposition results above, we model the SEDs of the *Forges* for different components, including the central AGN, host galaxy, and off-center emission (Methods). The best-model results show that the optical continuum of the central point source is well reproduced by a high-accretion SMBH surrounded by an optically thick photosphere with effective temperature $T_{\text{eff}} \sim 5000$ K^{16,40}. The $\sim 1\text{--}6$ μm emission excess requires an additional component with $T_{\text{eff}} \sim 500$ K that plausibly traces radiation from an emerging hot-dust torus. There is evidence that lower-redshift LRDs tend to exhibit enhanced IR emission compared to their high-redshift counterparts⁴¹, pointing to the onset of dust-torus formation. The *Forges* appear to represent a more evolved stage, where the dusty structure is substantially more developed. Attributing all the extended emission to stars would imply unrealistically high stellar masses ($> 10^{12} M_{\odot}$), suggesting a significant contribution from non-stellar light. The off-center emission is strong in the F200W and F277W bands, corresponding to [O III]/H β and H α , indicating photoionized gas³⁹. A stellar ionized nebula cannot reproduce such strong off-center emission as revealed by the SED fitting. We therefore consider only the central extended component (S \acute{e} rsic 1) as the host galaxy, while attributing the remaining off-center extended emission to gas clouds photoionized by the central AGN³⁹. The host galaxies have moderate star formation rates (SFRs) of 16.0 ± 0.9 and $77.7 \pm 6.6 M_{\odot} \text{yr}^{-1}$ and stellar masses of $\log(M_{*}/M_{\odot}) = 9.40 \pm 0.18$ and 10.28 ± 0.16 , consistent with the star-forming main sequence at $z \sim 3$ ⁴². They dominate the UV SEDs of the two objects. This is further supported by a pronounced 2175 \AA absorption feature that represents the presence of graphitic dust grains⁴³. For the off-center extended emission, we use CLOUDY to model the observed SEDs as nebular gas illuminated by the central AGN through an opening angle, exploring a grid of intrinsic AGN luminosities and nebular properties. The best-model intrinsic AGN UV luminosities are substantially higher than the observed UV luminosities of the point sources. In this scenario, the bulk of the UV emission from the center is absorbed by the optically thick photosphere and re-emitted as blackbody radiation with $T_{\text{eff}} \sim 5000$ K^{16,40}. Part of ionizing photons directly escape along the polar direction that is perpendicular to the line of sight, and photoionize the surrounding nebula⁴⁴. The intrinsic AGN UV luminosity inferred from the CLOUDY modeling of the nebular emission agrees with the observed optical–IR integrated luminosity (Extended Data Figure 6), validating an overall energy balance between the absorbed and reprocessed emission.

LRDs are often thought to be super-Eddington accreting SMBHs enshrouded in dense gas ($n_{\text{H}} \sim 10^9\text{--}10^{11} \text{cm}^{-3}$)^{9,17,27}, and their blue UV emission possibly arises from stellar population^{4,45,46} or photoionized nebular clouds³⁹. The *Forges* can be explained by this scenario in the context of evolution. The dense gas envelope around LRDs is expected to disperse and the LRD phase terminates due to feedback or accretion onto the central BH when M_{BH} becomes sufficiently large and the envelope structure can no longer be maintained^{16,46}. The *Forges* are witnessing this transitional phase during which LRDs are evolving into quasars. As shown in Figure 3, the SMBHs are overmassive compared with the local $M_{\text{BH}}\text{--}M_{*}$ relation, while their host galaxies are already well assembled and lie on the star-forming main sequence at $z \sim 3$. On the $L_{\text{bol}}\text{--}M_{\text{BH}}$ plane, the *Forges* start to deviate from the LRD population and share comparable L_{bol} and M_{BH} with lower-redshift quasars. LRDs at high redshift ($z \gtrsim 4$) are generally X-ray-weak, as they are embedded within the dense gas envelope that suppresses the escape of X-ray photons^{9,10,16,21,40}. In X-ray detected LRDs (e.g., Ref.⁴), including the *Forges*, the gas envelope is likely dispersing into a clumpy and porous structure. The emerging X-ray emission can escape along the line of sight, while most UV photons remain trapped (or dust reddened) owing to a much smaller X-ray cross-section and/or a smaller X-ray emission region. Radio jets are weakly confined, giving rise to the observed radio emission. Along the polar directions, the gas envelope is being cleared rapidly by AGN outflows, so UV ionizing photons escape easily through an opening angle and photoionize the surrounding gas⁴⁴. Meanwhile, a dust torus starts to form and dominate the mid-IR SED. At this evolutionary stage, different viewing angles yield

distinct observational properties. With this scenario, the *Forges* will eventually evolve into normal quasars. The evolutionary pathway and key observational properties from LRDs to quasars are summarized in Figure 4. From the contiguous slitless spectroscopy of COSMOS-3D, we identify seven broad He I LRDs at $z \sim 3$ (see Methods), two of which show the transitional properties as presented here. This implies that roughly 30% of LRDs at this epoch are observed in this short-lived stage, while the fate of the remaining LRDs remains unclear. Our finding provides a key link between some LRDs and normal AGNs.

Figures and Tables

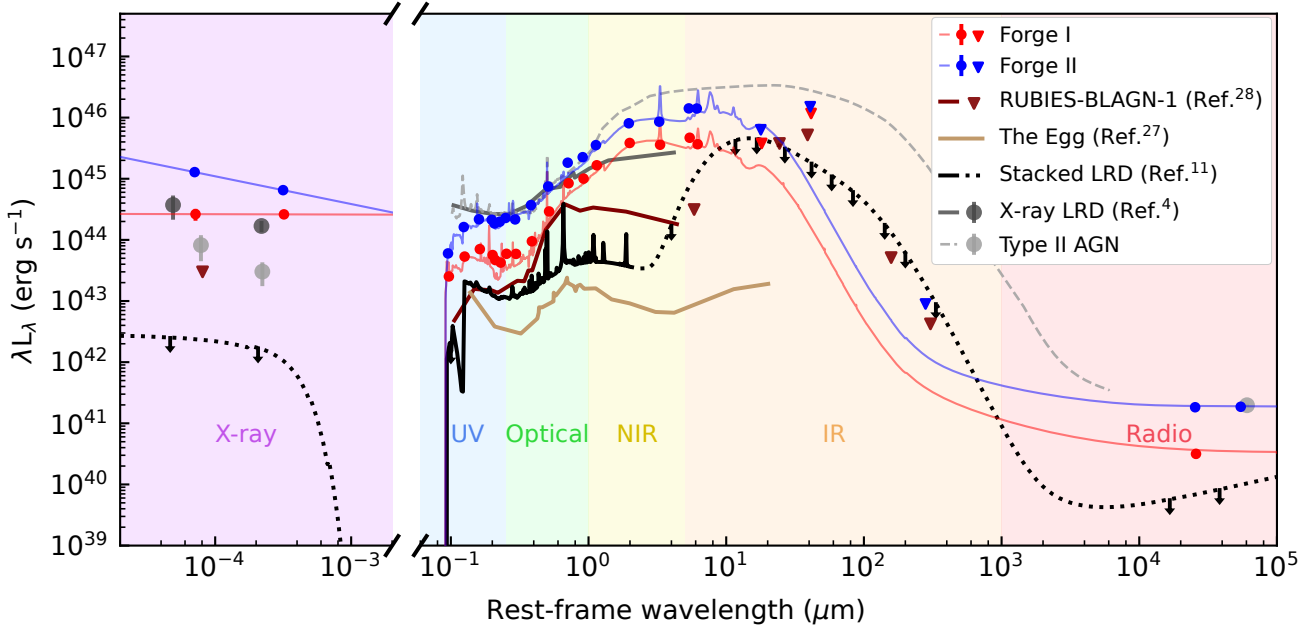

Figure 1. SEDs and multi-band images of the *Forges*. **Upper:** The X-ray to radio SEDs of the *Forges*. For reference, we also show the SEDs of other sources: a typical $z = 3.1$ LRD (RUBIES-BLAGN-1²⁸), a local LRD counterpart (*the Egg*²⁷), the stacked maximal COSMOS-Web LRD SED where the dotted line represents upper limits¹¹, another X-ray detected $z = 4.66$ LRD in COSMOS field⁴, and a highly obscured Type II AGN⁴⁷. **Lower:** Cutout images of the *Forge I* (left) and *Forge II* (right) spanning from X-ray to far-IR, including Chandra X-ray (0.5–7 keV), CFHT *U*, Subaru *grizy*, HST ACS F814W, JWST NIRCcam F115W, F150W, F200W, F277W, F356W, F444W, JWST MIRI F770W, F1000W, F2100W, and Spitzer MIPS 24, 70, and 160 μm bands. All cutouts are centered on the *Forges*.

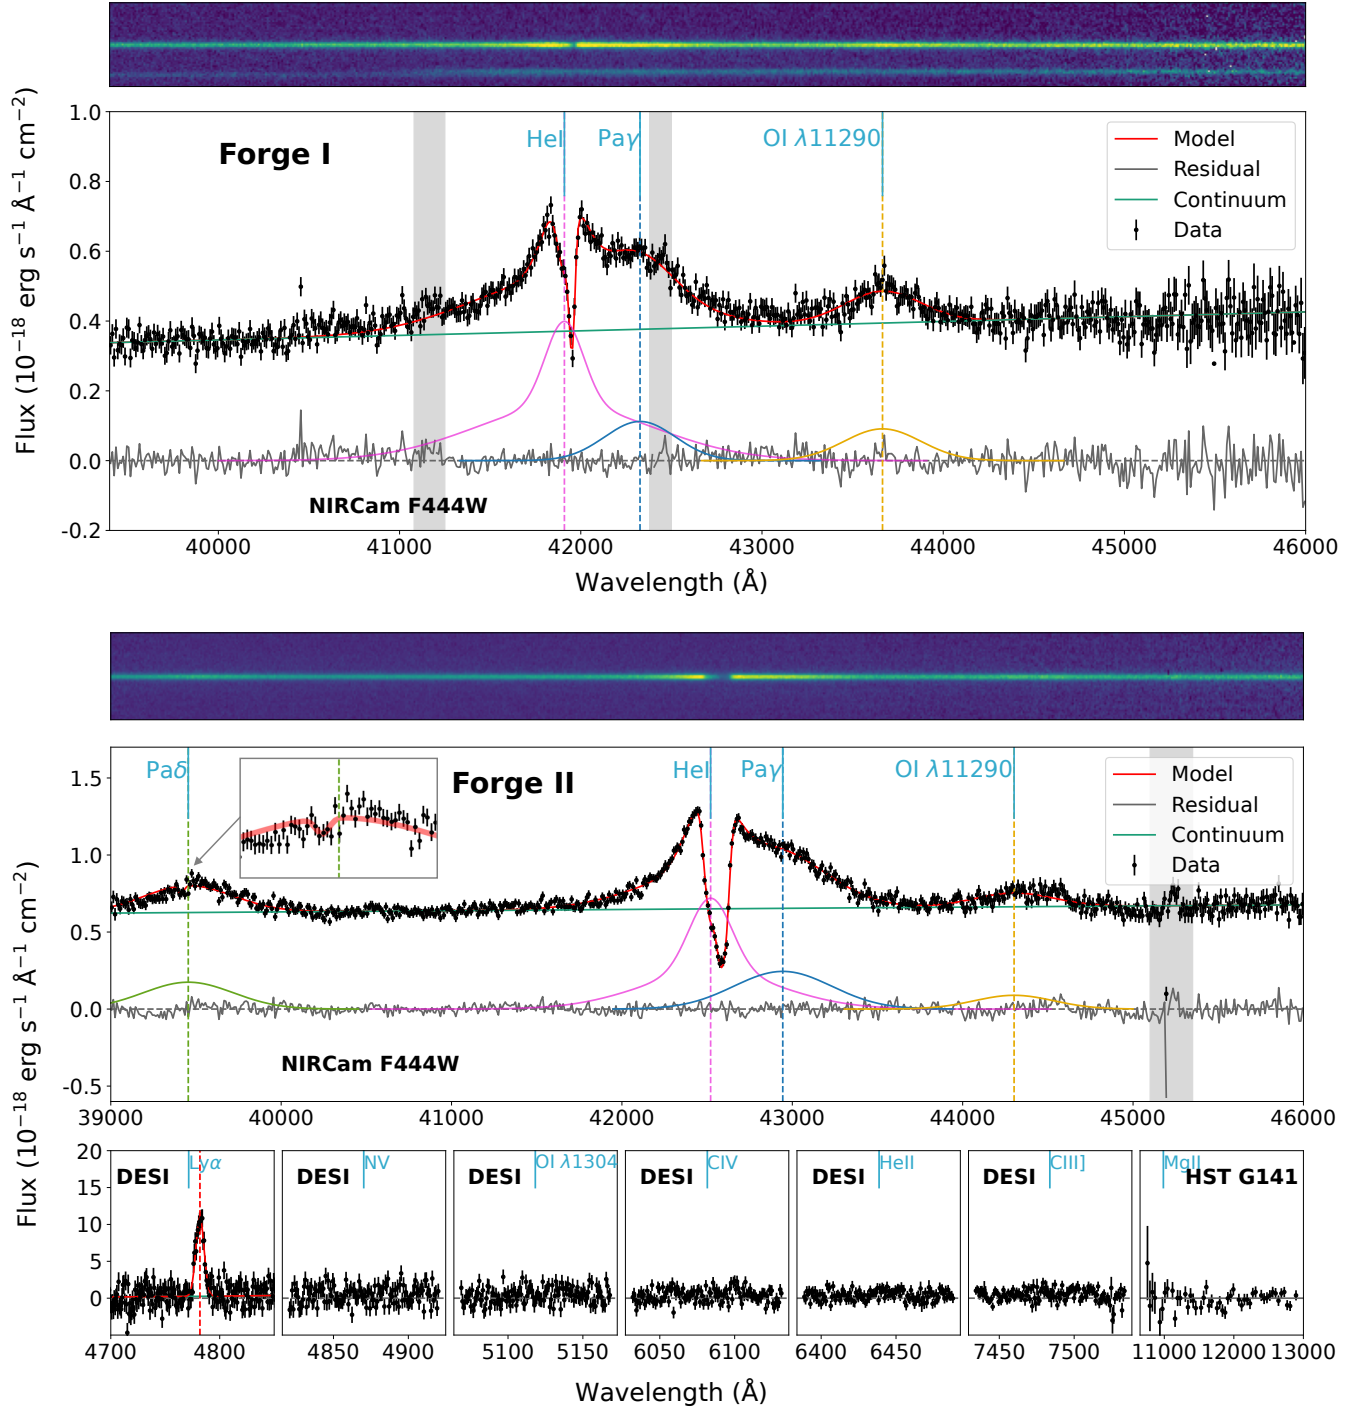

Figure 2. JWST NIRCcam F444W slitless spectra of the *Forges*. We also show the best-fit results and associated residuals. Prominent emission features (e.g., He I, O I λ 11287, Pa γ , Pa δ) are labeled. Short vertical lines at the top, labeled with line names, mark the theoretical positions of the emission lines. For *Forge II*, A zoom-in on the Pa δ absorption feature is shown in the subpanel, and additional spectroscopic coverage from DESI (covering the wavelength ranges of Ly α , N V, O I λ 1304, C IV, He II, and C III]) and HST G141 (Mg II) is also displayed. The gray-shaded regions indicate the wavelength ranges masked during the fitting process due to contamination from neighboring sources in the NIRCcam spectra.

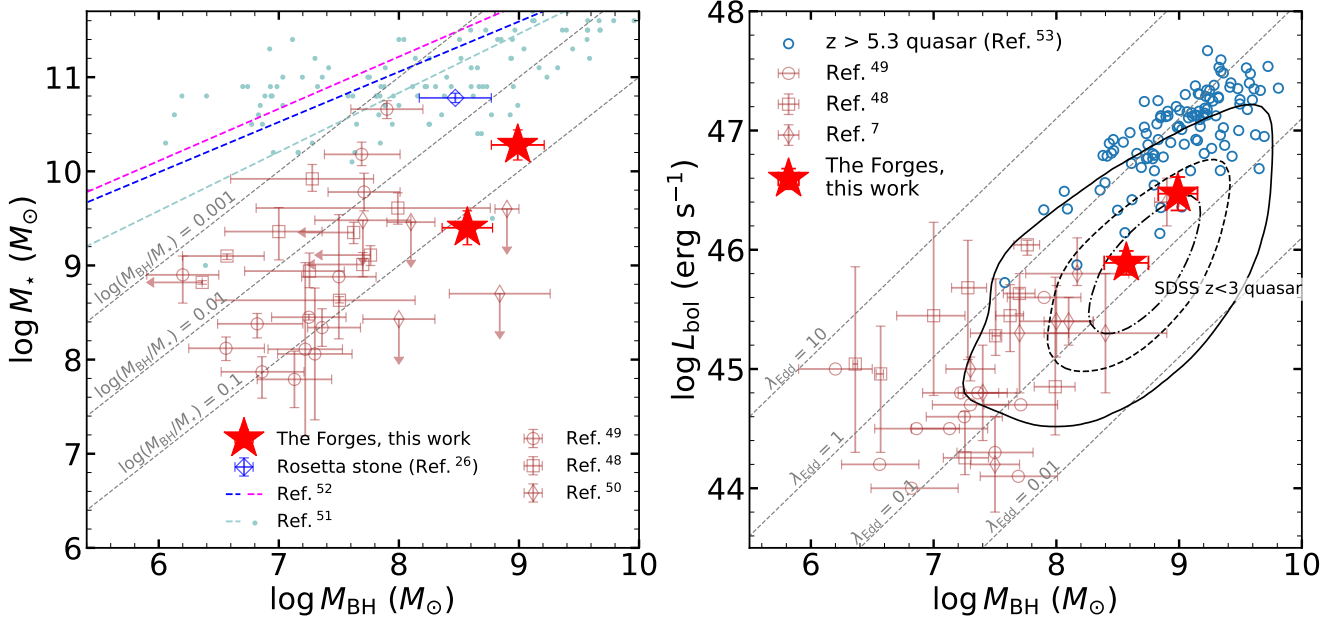

Figure 3. **Left:** M_* versus M_{BH} for the *Forges*, shown as red stars. For comparison, we include a few high-redshift LRD and AGN samples (brown symbols)^{48,49,50}, a $z = 2.26$ LRD (blue dot)²⁶, as well as local scaling relations: inactive galaxies (light blue dots and dashed line)⁵¹, AGN with early-type hosts (blue dashed line), and AGNs with late-type hosts (pink dashed line)⁵². The grey dashed lines denote constant $M_{\text{BH}}\text{-to-}M_*$ ratios. **Right:** L_{bol} versus M_{BH} . For comparison, we include high-redshift quasar (blue open circles)⁵³ and LRD/AGN samples (brown symbols)^{7,48,49}. The SDSS quasars with $z \leq 3$ are shown in the black contour⁵⁴. The grey dashed lines indicate constant Eddington ratios.

Figure 4. Comparison between LRDs, the *Forges* and typical quasars. The *Forges* occupy a transitional stage between LRDs and quasars.

Methods

Imaging and photometric data

JWST NIRC*am* and HST data. The *Forges* were observed by two JWST imaging programs: COSMOS-Web (GO#1727⁵⁵; PIs: J. Kartaltepe and C. Casey) and COSMOS-3D (GO#5893; PI: K. Kakiichi) using the near-IR Camera⁵⁶ with filter bands of F115W, F150W, F200W, F277W, F356W, and F444W. We reduced the NIRC*am* imaging data following the steps in Ref.²⁰. Briefly, we reduced the raw data using the combination of the *JWST Calibration Pipeline* (v.1.17.0) with CRDS version 11.17.0 and CRDS context 1185, the CEERS⁵⁷ NIRC*am* imaging reduction¹ and our own custom codes. All images were aligned to the HST images from the HST COSMOS survey². These HST images were also included in our analyses below. The final NIRC*am* and HST images have a pixel scale of 0.''03.

JWST MIRI data. The MIRI images of the two LRDs were observed by COSMOS-Web (F770W) and COSMOS-3D (F1000W and F2100W). We reduced the MIRI data using the *JWST Calibration Pipeline* (v.1.17.0) with CRDS version 11.17.0 and CRDS context 1185. Our reduction pipeline is based on the public CEERS pipeline^{58,3} with several custom steps to improve data quality. The details can be found in Ref.²⁰ In addition to the standard Stages 1 and 2 processing, we removed the horizontal and vertical stripes after Stage 2 and mitigated warm-pixel contamination by masking pixels identified in median-stacked images. We also adopted a modified background-subtraction scheme⁵⁹, in which a super-background was constructed from other exposures with sources masked, followed by a large-scale filtering. All images were aligned to the NIRC*am* F444W mosaic image. The final MIRI images have a pixel scale of 0.''06.

Subaru, CFHT, and Spitzer data. We used Ultradeep optical (*grizy*) imaging data from the Hyper Suprime-Cam Subaru Strategic Program⁶⁰ third public data release (PDR3). We incorporated the CFHT *U*-band images from the MUSUBI (MegaCam Ultra-deep Survey: *u**-band Imaging) survey⁶¹. At longer wavelengths, we included Spitzer MIPS 24, MIPS 70, and MIPS 160 images from the S-COSMOS survey⁶².

For the JWST NIRC*am* and HST images, we constructed empirical PSF models for each band using `PSFEX`⁶³, following the method in Ref.⁶⁴. We used these PSFs to derive kernels to match all PSFs to the F444W PSF using `PyPHER`⁶⁵, and then used them to convolve all images to match the F444W image. Next, we performed photometry using `SExtractor`⁶⁶ on the PSF-matched images to construct source catalog. We used the dual image mode and the detection image is a χ^2 image combining the PSF-matched NIRC*am* images. Photometry is measured in a small Kron aperture ($k=1.1$, $R_{\min}=1.6$), and an aperture correction is performed to match the default Kron aperture ($k=2.5$, $R_{\min}=3.5$) in each band. The photometric errors is measured following the method in Ref.⁸ by placing random apertures.

For the HSC and CFHT images, we derived template-fitting deblending photometry to get the total fluxes at each band with T-PHOT v2.0⁶⁷. T-PHOT uses position priors from the high-resolution NIRC*am* F444W images. We generated PSF models for the NIRC*am*, HSC, and CFHT images using `PSFEX`, and constructed convolution kernels to match the NIRC*am* F444W PSF to those of the HSC and CFHT images. These kernels were used to build image templates for each source, from which the photometry in each band is extracted through template fitting with T-PHOT.

The MIRI and Spitzer images have much larger PSFs than those of the other bands, so the sources are unresolved. We performed aperture photometry and applied aperture corrections separately. For the MIRI data, we adopted an aperture radius corresponding to 65% of the encircled energy as given in Ref.⁵⁹, followed by an aperture correction. The photometric uncertainties were estimated from the

¹<https://github.com/ceers/ceers-nircam>.

²https://irsa.ipac.caltech.edu/data/COSMOS/images/acs_mosaic_2.0/.

³<https://github.com/ceers/ceers-miri>.

background fluctuations within an annulus larger than the PSF size with other sources masked. For the Spitzer images, we applied a similar procedure using the recommended aperture radius, aperture correction, and background annulus⁴.

VLA data. The two sources were detected in the VLA-COSMOS deep 3 GHz survey³⁶. The synthesized beam size is $0''.75$ (circularized) across the two-square-degree field. The local rms at the source positions is $2.3 \mu\text{Jy beam}^{-1}$ for *Forge I* and $2.23 \mu\text{Jy beam}^{-1}$ for *Forge II*. *Forge I* has a flux density of $15.2 \pm 2.4 \mu\text{Jy}$, and was classified as *unresolved* in the catalog. *Forge II* has a flux density of $83.9 \pm 4.8 \mu\text{Jy}$, and is *resolved* with a size over several synthesized beams.

In the 1.4 GHz VLA-COSMOS Large Project catalog³⁷, *Forge II* (COSMOSVLA_J095934.07+021706.4) has an integrated flux density of $183 \pm 25 \mu\text{Jy}$ and a deconvolved size of $1''.10 \times 0''.41$ at a position angle of 124° , corresponding to a linear size of ~ 9 kpc. The rms at the radio source position is $0.178 \text{ mJy beam}^{-1}$. The synthesized beam size is $1''.5 \times 1''.4$.

From the 1.4–3 GHz flux ratio, we derived a radio spectral index of $\alpha = -1.02 \pm 0.19$ (where $f_\nu \propto \nu^\alpha$), consistent with the distribution of spectral indices in large radio AGN samples (mean $\alpha = -0.73$, $\sigma = 0.35$ ³⁶). Adopting this spectral index for both sources yields radio-loudness parameters of $R = 28.3$ and $R = 48.5$, where $R = f_{5\text{GHz}}/f_{4400\text{\AA}}$ ⁶⁸ and $f_{4400\text{\AA}}$ is derived from the F115W and F200W-band flux. As described in the SED modeling section of the Methods, a large fraction of the $f_{4400\text{\AA}}$ flux from the accretion disk of the central AGN is absorbed along the line of sight and re-emitted in the rest-frame optical and near-IR. Consequently, these R values are overestimated. If we instead adopt the intrinsic $f_{4400\text{\AA}}$ inferred from the ionized nebular model (Extended Data Figure 6), the radio loudness values decrease to $R = 5.2$ and 1.5 that are both below the conventional threshold for radio-loud AGNs ($R > 10$).

ALMA data. *Forge II* was covered by an archival ALMA program (PID 2024.1.01085.S). The observation was made on band 6 with an integration time of 890 s. We used the publicly available ALMA continuum images from the A³COSMOS project⁶⁹, which systematically reprocessed all archival ALMA observations in the two-square-degree COSMOS field to produce homogeneous, high-sensitivity (sub)millimeter maps. The A³COSMOS ALMA continuum images were produced with the CASA pipeline⁷⁰ (v4.7.2) in “continuum” + “automatic” mode with Briggs weighting (robust = 2) and multi-frequency synthesis (nterms = 2). These maps achieve on average $\sim 10\%$ better rms sensitivity than the official ALMA QA2 products, with typical angular resolutions characterized by a synthesized beam major-axis FWHM of $\sim 1''$. *Forge II* was not detected in the ALMA image. We estimated the rms value at the position of *Forge II* and corrected the PB value, resulting in a 2σ upper limit of $30 \mu\text{Jy}$.

Spectroscopic data

JWST NIRCcam slitless spectra. COSMOS-3D (GO5893, PI: K. Kakiichi) obtained NIRCcam WFSS observations of the COSMOS field using the row-direction grism (Grism R) combined with the wide-band filter F444W. The WFSS data were reduced following the standard procedure⁷¹, and the corresponding codes and calibration files are publicly available⁵. We first processed the NIRCcam WFSS data using the standard JWST Stage-1 calibration pipeline (version 1.13.4) and the calibration reference file `jwst_1364.pmap`. A flat-field correction was applied using flat-field data obtained with the same filter and detector. For each exposure, we constructed and subtracted a super-sky background using all flat-fielded exposures taken with the same filter+pupil+module combination. Residual background structure remained after this step, so we performed an additional 2D sky-background subtraction using the Source Extractor algorithm⁶⁶. The background was estimated on the 2.5σ -clipped image using a mode estimator of the form $(2.5 \times \text{median}) - (1.5 \times \text{mean})$, which is less sensitive to source crowding

⁴<https://cosmos.astro.caltech.edu/page/spitzer>.

⁵https://github.com/fengwusun/nircam_grism

than a simple clipped mean. If $(\text{mean} - \text{median})/\text{STD} > 0.3$ (where STD denotes the standard deviation), the mode estimator becomes unreliable and a simple median is used instead. Finally, the astrometry of the grism data was refined by matching the simultaneously obtained short-wavelength images to the long-wavelength source catalog, which had previously been registered to the HST catalog.

HST G141 and DESI spectra. 3D-DASH (GO16259/16443, PI: Ivelina Momcheva) observed the entire 1.7 deg^2 COSMOS field with the broadband images in WFC3 F160W and the parallel slitless spectroscopy in WFC3 G141. It covered *Forge II* with both direct images and slitless spectroscopy. Each mode took 1774 s of exposure time. We reduced the spectrum using the pipeline GRIZLI⁶, similar to the procedure in previous works⁷². We first downloaded the data from MAST. The raw exposures were bias- and dark-subtracted and flat-fielded. Preprocessing steps included calibrating the WCS of each direct+grism image pair, coadding the drizzled images, aligning the grism exposures when multiple position angles were available, and subtracting the background. A photometric catalog was constructed from the direct images for subsequent extraction. For each detected source, an initial flat continuum scaled to its broadband flux was assigned; for bright sources, the model was iteratively refined to higher-order polynomials by direct spectral fitting. This process produced the contamination model, which was subtracted from each grism image. The 2D beam of our target sources were then extracted with forward modeling: for all beams overlapping the targets, we ranked them by the F160W luminosity. Starting from the brightest, we iteratively extracted their 2D beams, fitted continuum models, and subtracted them from the target beam. Finally, using the 2D morphology of the source in F160W, we defined the extraction aperture and derived the final 1D spectrum. *Forge II* is also covered by DESI spectroscopic observations, and we obtained its DESI spectrum from the archive⁷³.

Spectral fitting

We model the F444W slitless spectra of both sources using a power-law continuum, multiple Gaussian components for the emission lines, and a standard attenuation model for the He I and Pa δ absorption features. The emission line set includes He I (broad and narrow components), Pa γ , Pa δ , and O I λ 11287. Assuming the source is fully covered by the absorber, the absorption features are modeled using⁷⁴

$$f_{\lambda} = e^{-\tau_{\lambda}}, \quad (1)$$

where τ_{λ} is the optical depth profile

$$\tau_{\lambda} = \tau_0 \exp \left[-0.5 \left(\frac{\lambda - \lambda_0 e^{\Delta v/c}}{\sigma} \right)^2 \right], \quad (2)$$

in which τ_0 is the optical depth at the core of the line, Δv is the velocity shift of the absorber and σ is its velocity dispersion. For He I, the absorption trough shows an asymmetric profile, therefore two absorption components are required. For *Forge II*, Pa δ also shows a blueshifted absorption feature, which is fitted with one absorption model. All emission line components are fitted with their central wavelengths tied to a common systemic redshift parameter. For *Forge II*, we additionally link the line widths of Pa γ and Pa δ to reduce the degeneracy due to blending and low signal-to-noise ratio (S/N). We perform a Markov chain Monte Carlo likelihood fit using `emcee` to constrain the model parameters. The wavelength ranges in the NIRCcam slitless spectra that are contaminated by emission lines from neighboring sources are masked during the fitting.

The fitting result is shown in Figure 2 and the key emission and absorption line properties are summarized in Extended Data Table 1. The detection of deep and slightly redshifted He I absorption troughs

⁶<https://grizli.readthedocs.io/en/latest/>

suggests inflowing material or fallback motions, rather than the commonly observed large blueshifted outflows in many AGNs. Meanwhile, the marginally detected blueshifted Pa δ absorption further indicates a complex multi-component absorbing system. The column density of the absorbers are computed as⁷⁴

$$N = \frac{m_e c}{\pi e^2 f_0 \lambda_0} \tau, \quad (3)$$

where τ is the integrated line optical depth and $f_0 \lambda_0$ is the product of the oscillator strength of the transition and the rest-frame wavelength. The calculated values of $N_{\text{He}}(2^3\text{S})$ are shown in Table 1, which are in the order of $\sim 10^{13.5} \text{ cm}^{-2}$. The estimated $N_{\text{He}}(2^3\text{S})$ values are consistent with those reported in other LRDs^{26,28,75}. A detailed analysis of the strong He I absorption system in the *Forge II* is also presented in Z. Li et al. (submitted), who report *Forge II* and another object as obscured X-ray AGNs. They further calculate the density of the absorbing gas of *Forge II* as $\log(n_{\text{H}}/\text{cm}^3) = 10$, with a distance of $\sim 0.02 \text{ pc}$ to the ionizing source. These density and distance is comparable the expectation of the dense envelope of LRDs^{16,17,27}, suggesting that the absorbers may be related to the envelope. He I absorption probes partially ionized, high-column density gas with a large amount of helium pumped to the long-lived metastable triplet state 2^3S . In contract, Pa δ absorption requires a significant population of hydrogen in the short-lived $n = 3$ level. Like Balmer absorption, it forms only in high-density excited gas, much less frequently than He I absorption^{26,28}. Future JWST/NIRSpec MSA G395H observations will provide deeper and contamination-free spectra than the existing NIRCам WFSS data and enable a more detailed investigation of the absorbers and the properties of the ionizing radiation field.

The black hole masses estimated from Pa γ and Pa δ ³⁰ are $M_{\text{BH}} = (3.70 \pm 1.85) \times 10^8 M_{\odot}$ for *Forge I* and $(9.75 \pm 4.88) \times 10^8 M_{\odot}$ for *Forge II*, with additional 50 percent uncertainty included to account for the intrinsic scatter of the calibration³⁰. These estimates assume that the lines are Doppler-broadened by the virial motion of gas in the broad-line region (BLR), and the BLR size is calibrated using local Type I AGNs. It remains uncertain whether the gas is truly virialized and whether LRDs follow the same radius–luminosity relation as Type I AGNs. Such assumptions may introduce systematic uncertainties of up to one order of magnitude^{40,76,77}.

According to some theoretical models for growing seed BHs²⁹, the O I $\lambda 11287$ line arises from Ly β fluorescence pumping followed by a cascade⁷⁸, tracing a high-density partially neutral zone in the outer disk or the inner broad-line region. Given the detection of the O I $\lambda 11287$ line, we would also expect to observe the O I $\lambda 1304$ and O I $\lambda 8446$ transitions, which arise from the same cascade process. The O I $\lambda 1304$ line of the *Forge II* is covered by the DESI spectra, but is not detected ($\leq 2\sigma$); the O I $\lambda 8446$ is not covered in the current spectra. If resonance fluorescence by Ly β is the sole dominant mechanism, the photon flux ratio between O I $\lambda 11287$ and O I $\lambda 1304$ should be unity, corresponding to a flux ratio of 8.7. In this case, the O I $\lambda 1304$ line would have been detected in the DESI spectrum with a S/N of about 44. Several effects can significantly alter this ratio, such as strong UV reddening^{78,79}. In addition, Ref.⁷⁹ describes three processes that can destroy O I $\lambda 1304$ photons: (1) O I $\lambda 1304$ photons can photoionize H I atoms in the $n = 2$ state, (2) collisional de-excitation can destroy O I $\lambda 1304$ photons, and (3) the upper $3s \ 3^3\text{S}^0$ level can decay to the metastable terms of the ground configuration via the intercombination lines O I] $\lambda 1641$ and O I] $\lambda 2324$. In fact, their calculations show that up to half of the O I $\lambda 1304$ photons can be converted into O I] $\lambda 1641$ ⁷⁹. The *Forge II* was also observed by the LATIS Survey⁸⁰, in which the $R \sim 1000$ IMACS spectra (12-hour integrations) cover 3890–5830 Å, corresponding to 991–1485 Å in the rest frame of the *Forge II*. The LATIS data independently confirm the absence of any detectable O I $\lambda 1304$ emission, consistent with the DESI result.

Image decomposition

The JWST NIRC*am* images reveal that the two sources are compact in the long-wavelength channels and extended in the short-wavelength channels. To quantitatively characterize their morphology, we perform multi-band image decomposition with `GalfitM`^{81,82} following the standard routine^{52,83}. The decomposition is performed in six NIRC*am* bands (F115W, F150W, F200W, F277W, F356W, and F444W). Contaminant sources are manually masked to ensure that the fitting process focuses on the central targets. Using `PSFEX`⁶³ and following the strategy in Ref.⁶⁴, we construct empirical PSF models by stacking bright, isolated, and unsaturated point sources in the local mosaic region around our targets. Both sources are initially modeled with a PSF component for the AGN and a single Sérsic component for the host galaxy. After the initial fitting process, both sources exhibit substantial off-center residuals in the model-subtracted F200W and F277W images, corresponding to the wavelengths with strong nebular emission lines such as [O III]/H β and H α . Therefore, we decide to include an additional Sérsic component in all bands.

In the main fitting process, we first use the python codes `statmorph`⁸⁴ and `photutils`⁸⁵ to estimate the position, morphology, and magnitudes for the point source and host galaxy components. The derived values are fed to `GalfitM` as input parameters. The PSF position of each source is constrained to be within ± 1 pixel around its peak pixel (x_{peak} , y_{peak}) to ensure that the PSF is fitted to the peak of our targets. For the two Sérsic components, the positions of one Sérsic have initial offsets from the (x_{peak} , y_{peak}) to better fit the offset fluxes. To minimize possible degeneracy, we constrain the Sérsic index n to be less than 8 and the half-light radius to be larger than 4. We perform two iterations of the `GalfitM` fitting to improve the fitting results. After the first iteration, we use the PSF-subtracted images to refine the morphological model of the host galaxy. The derived parameters serve as inputs for the second iteration.

Extended Data Figures 1 and 2 show the multi-band image decomposition results. The photometric and morphological parameters are listed in Extended Data Table 2. The morphological parameters of Sérsic components, including the effective radius R_e , the Sérsic index n , and the positional offset from the PSF center, are the median values measured across all bands. Because a single Sérsic component provides an imperfect description of the complex off-center extended emission, we subsequently perform aperture photometry at the location of the second Sérsic component on the residual image Data–PSF–Sérsic 1. The nebular flux used in the following SED modeling is taken from these aperture measurements. The fitting results confirm that in the short-wavelength bands ($\lambda_{\text{obs}} \leq 2 \mu\text{m}$, corresponding to rest-frame $\lambda_{\text{rest}} \lesssim 5000 \text{ \AA}$), the emission is dominated by the extended Sérsic components, indicating that the host galaxy contributes the majority of the flux in the rest-frame optical and UV regime. In contrast, the long-wavelength bands ($\lambda_{\text{obs}} > 2 \mu\text{m}$, corresponding to rest-frame $\lambda_{\text{rest}} > 5000 \text{ \AA}$) exhibit an enhanced point-source contribution from the AGN.

SED modeling

After performing the two-dimensional decomposition of the NIRC*am* images with `GalfitM`, we separate the host galaxy, off-center emission, and the central AGN components, and then model them independently. A significant fraction of LRDs exhibit off-center and extended emission. In a systematic study of 99 photometrically selected LRDs at $z \approx 4\text{--}8$, about 30% were found to exhibit a variety of complex, extended UV morphologies beyond the dominant central point sources⁸⁶. It is proposed that such off-center emission could arise from nebular emission powered by the central AGN³⁹, rather than by ionization from young stars. For the *Forges*, attributing all the extended emission to the host galaxy would yield an unrealistically high stellar mass, exceeding $10^{12} M_{\odot}$ (see also Z. Li et al., submitted). This suggests that at least part of the extended light is unlikely to be stellar in origin. Consistent with this, the off-center emission is particularly strong in the F200W and F277W bands, corresponding to the wavelength ranges of [O III]/H β and H α , indicating a potentially non-stellar source of ionization. We therefore model the off-center extended emission (Data–PSF–Sérsic 1) in the NIRC*am* images

(Table 2) as gas clouds photoionized by AGN. We compute a grid of spectral templates using the spectral synthesis code CLOUDY⁸⁷. An open-angle geometry with the inner and stop radii are set to be $R_d - R_e$ and $R_d + R_e$, respectively, where R_d is the distance from the central point source. For the input ionizing spectrum, we adopt a typical AGN intrinsic UV continuum ($T = 10^6$ K, $\alpha_{\text{ox}} = -1.4$, $\alpha_{\text{UV}} = -0.5$, and $\alpha_{\text{X}} = -1$, see Section 6.2 of Hazy1⁷) with the total AGN luminosity L_{AGN} treated as a free parameter. We assume that a fraction of the UV radiation from the central AGN escapes through a small opening angle of the gas envelope and ionizes the nebula, while the rest is absorbed by the envelope. This fraction is called a covering factor. We derive the covering factor from the solid angle subtended by the off-center Sérsic component as seen from the PSF component, using its effective radius and projected distance from the PSF component. We then compute spectra with different combinations of total AGN luminosity ($\log[L_{\text{AGN}}/(\text{erg s}^{-1})] = 44\text{--}48$ in steps of 0.5 dex), gas density ($\log[n/\text{cm}^{-3}] = 1\text{--}5$ in steps of 1 dex), and metallicity ($Z = 0.005, 0.02, 0.2, 0.4$, and $1 Z_{\odot}$), and apply the intergalactic medium absorption to the output. We perform Least-squares fitting to identify nebular parameters that best reproduce the observed SEDs of the secondary Sérsic component. The best-fit nebular parameters are $\log[L_{\text{AGN}}/(\text{erg s}^{-1})] = 45.5$, $\log[n/\text{cm}^{-3}] = 4$, and $Z = 1.0 Z_{\odot}$ for *Forge I*, and $\log[L_{\text{AGN}}/(\text{erg s}^{-1})] = 47.0$, $\log[n/\text{cm}^{-3}] = 5$, and $Z = 0.4 Z_{\odot}$ for *Forge II*.

As shown in Extended Data Figure 3, the decomposition of the NIRCcam images reveals a clear decrease in the point-source contribution from the rest-frame near-IR towards the optical–UV bands. We assume that the same trend holds in the UV bands, where the limited image resolution prevents reliable decomposition. These UV bands are dominated by the extended components instead of the central PSF. For the lower-resolution HSC and CFHT images, we derive the galaxy flux by subtracting the modeled nebular emission from the total observed flux, and include these measurements in the SED fitting procedure together with the NIRCcam bands. We fit the host galaxies with the SED fitting code CIGALE (v2025;⁸⁸). We adopt a delayed star formation history with a possible bursty, Bruzual and Charlot (2003) stellar population synthesis models⁸⁹, nebular emission, and a modified Calzetti dust attenuation law⁹⁰. We include a 2175 Å UV bump to the attenuation curve $A(\lambda)/E(B - V)$, modeled with a Lorentzian-like Drude profile characterized by three parameters: the central wavelength, FWHM, and amplitude. The FWHM and amplitude are allowed to vary during the fitting. The dust emission is modeled with the Draine et al. (2014)⁹¹ framework, which treats dust as a mixture of silicate, graphite, and PAHs illuminated by a radiation field ranging from U_{min} to U_{max} following a power-law index α . The PAH mass fraction (q_{PAH}) and the dust mass fraction associated with star-forming regions (γ) are also treated as free parameters. To account for uncertainties from the image decomposition, we add a relative error of 5% in quadrature to all photometric flux uncertainties. Non-detections in Spitzer MIPS 70 μm and 160 μm (and in ALMA⁹² for *Forge II*) are included as upper limits. As shown in Extended Data Figure 3, the dust emission from the host galaxies dominates at the rest-frame $\sim 10 \mu\text{m}$, while additional hot dust is required to explain the emission at $\sim 1\text{--}6 \mu\text{m}$, which cannot be produced by the galaxy alone and is therefore likely contributed by the central AGN.

For the central AGNs, besides the decomposed NIRCcam photometry, we also include JWST MIRI F770W, F1280W, F2100W, and Spitzer MIPS 24 μm photometry⁹³ in the SED model. The AGN flux in the MIRI and Spitzer MIPS bands is calculated by subtracting the modeled galaxy dust emission from the total observed flux. We adopt the geometrically thick, quasi-spherical super-Eddington accretion model proposed by Ref.⁴⁰ to interpret the unique SED of the LRDs. To reproduce the hot dust emission at $\sim 1\text{--}6 \mu\text{m}$, we introduce a blackbody component with a characteristic temperature of $T \sim 500$ K.

The SED modeling results are shown in Extended Data Figure 3, and the inferred key parameters

⁷https://gitlab.nublado.org/cloudy/cloudy/-/tree/master/docs/latex?ref_type=heads

are summarized in Table 1. The characteristic V-shape observed in the total SEDs is well-modeled by nebular and stellar-dominated emission in the rest-frame UV and LRD gas envelope-dominated emission in the rest-frame optical to near-IR. The bolometric luminosities of the central AGNs are estimated by integrating the reprocessed SEDs of the central point sources, under the assumption that their contribution is negligible in the rest-frame UV due to absorption and reprocessing by the gas envelope.

The intrinsic UV budget of the AGNs can be estimated from the CLOUDY fitting result of the nebular emission, which is consistent with the observed optical–IR reprocessed emission from the perspective of energy conservation. Previous studies have shown that the dust-to-gas ratio in the nuclear regions of AGNs is highly variable⁹⁴. Assuming a Galactic dust-to-gas ratio of $\log[E(B - V)/N_{\text{H}} (\text{mag cm}^2)] = -21.8$, we estimate $E(B - V)$ values from N_{H} derived through X-ray spectral fitting. Applying this $E(B - V)$ and the Calzetti dust extinction law⁹⁰ to the intrinsic UV SED of the AGN with normalization derived from the CLOUDY fitting of the nebular emission, we obtain the attenuated UV SED shown in Extended Data Figure 6. As expected, the UV emission from the central AGN is almost completely absorbed, with the absorbed energy consistent with the observed optical–IR reprocessed emission. This implies that, assuming a typical dust-to-gas ratio for the obscuring envelope, X-ray photons from the AGN can still penetrate and be detected, while the UV photons remain trapped and are re-emitted as the observed optical–IR emission. We note that the dense atmospheric gas itself also traps UV emission due to the large optical depth⁴⁰, therefore the real dust-to-gas ratio may be smaller than what we have applied.

X-ray data reduction

The *Forges* both have multiple XMM-Newton observations during 2004–2006 from the XMM-Newton Wide-Field Survey in the COSMOS Field³³. They also have archival Chandra observations at 2007 from the Chandra Cosmos Legacy Survey³⁴. These data enable study of their X-ray variability. We reduced the raw data of these observations following the method in Ref.⁹⁵.

For the XMM-Newton data reduction, we processed the X-ray data using the XMM-Newton Science Analysis System SAS v.20.0.0⁹⁶ and the latest calibration files. All the EPIC pn, MOS1, and MOS2 data were used in our study when available. We reduced the pn and MOS data following the standard procedure described in the SAS Data Analysis Threads.⁸ Background flares were filtered to generate cleaned event files. For most of the observations, our sources are detected in both the pn and MOS images. In a few observations, the target may be outside the field of view of one or two detectors. For each observation of each source, a source spectrum was extracted using a circular region with a radius of 30'' centered on the optical source position. A corresponding background spectrum was extracted from a few nearby circular source-free regions on the same CCD chip with a total area of about four times the area of the source region. Spectral response files were generated using the RMFGEN and ARFGEN tasks. We grouped the source spectra with at least one count per bin, since the total spectral counts numbers in the 0.3–10 keV band combining the pn and MOS spectra for all observations are smaller than 300⁹⁵. This results in 6 epochs and 5 epochs of XMM-Newton spectra for *Forge I* and *Forge II*, respectively. We also stacked the XMM-Newton spectra of each source to achieve higher S/N.

To reduce the Chandra data, we used the Chandra Interactive Analysis of Observations (CIAO; v4.15)⁹ tool. We first used the CIAO CHANDRA_REPRO script to create new bad-pixel files and new level 2 event files. Background flares were removed using the DEFLARE script with an iterative 3σ clipping algorithm. Then a source spectrum was extracted using the SPEXTRACT tool from a circular region centered on the optical position. The radius of the circle was chosen to enclose 90% of the PSF at 1 keV using the PSF command. A background spectrum was extracted from an annular region centered on the source position,

⁸<https://www.cosmos.esa.int/web/XMM-Newton/sas-threads>.

⁹<http://cxc.harvard.edu/ciao/>.

with the inner and outer radii chosen to be the source radius plus $4''$ and $8''$, respectively. We have visually inspected the background-extraction regions and verified that they did not contain any X-ray sources. We combined the extracted Chandra spectra of each source using COMBINE_SPECTRA since they were all observed within several days. Chandra spectra were also grouped with at least one count per bin.

The X-ray spectra of were fitted using XSPEC⁹⁷ (v12.12.1) with the W statistic (W -stat).¹⁰ In order to check the variability of these two sources, we first adopted a simple power-law model modified by Galactic absorption (ZPOWERLW*PHABS) to describe the multi-epoch 0.3–10 keV XMM-Newton spectra or 0.5–7 keV Chandra spectra. For the XMM-Newton observation, we jointly fitted the available EPIC pn, MOS1, and MOS2 spectra. We also added normalization constants (best-fit values between 0.7 and 1.3) to the MOS spectra to account for small cross-calibration uncertainties. The simple power-law model can describe all the spectra well. The combined XMM-Newton spectra are shown in Figure 4. For *Forge II*, a Fe $K\alpha$ line at a rest-frame energy of 6.4 keV is detected with a confidence level of 98.4% ($p = 0.016$; estimated using the LRT command of XSPEC) and a moderately large rest-frame EW of 0.71 keV, indicating the presence of dense, cold material that reflects hard X-rays in the vicinity of the nucleus. For *Forge I*, we did not detect significant Fe $K\alpha$ line (confidence level of 62.7%, $p = 0.373$) due to its lower luminosity. From the best-fit power-law models, we computed the rest-frame 2 keV flux densities ($f_{2\text{keV}}$), 10 keV flux densities ($f_{10\text{keV}}$), and 2–10 keV luminosities (L_X) of each source in each epoch. The derived X-ray light curves of the two sources are shown in Figure 5, with the black dashed lines and gray shaded regions showing the fitted values and errors of the stacked XMM-Newton spectra using the same model. Both *Forge I* and *Forge II* display some levels of X-ray variability. *Forge I* exhibits significant variability with a maximum amplitude of $5.4_{-2.7}^{+37.8}$ in $L_{2-10\text{keV}}$ over a timescale of ~ 2 years in the observed frame, whereas *ForgeII* shows a modest variability amplitude of $1.7_{-1.0}^{+0.8}$ over ~ 0.5 years. To characterize their absorption level, we fitted the stacked XMM-Newton spectra with an intrinsic absorption component (ZPHABS), and the photon index of the intrinsic power-law was a free parameter. The best-fit N_{H} are $2.1_{-1.3}^{+1.8} \times 10^{22} \text{ cm}^{-2}$ and $1.4_{-1.3}^{+1.8} \times 10^{22} \text{ cm}^{-2}$, with intrinsic photon indices of $2.4_{-0.5}^{+0.4}$ and $1.5_{-0.2}^{+0.3}$. These column densities indicate a modest level of obscuration.

The $\alpha_{\text{ox}} - L_{2500}$ relation and Fundamental plane

The UV-to-X-ray power-law spectral slope, α_{ox} , is a widely used indicator of the strength of ionizing emission in quasars. Large quasar samples have revealed a tight correlation between α_{ox} and the rest-frame 2500 Å luminosity, L_{2500} . We estimate the intrinsic L_{2500} of the central AGNs by modeling their ionized nebular emission (see SED modeling). As shown in the left panel of Fig. 7, the *Forges* lie on the $\alpha_{\text{ox}} - L_{2500}$ relation defined by the general quasar population, indicating that their central AGNs are approaching the typical quasar regime. In contrast, the observed total L_{2500} values fall beyond the 3σ scatter of the relation, suggesting that the observed UV emission is dominated by the host galaxy and nebular components rather than the AGN itself.

Another well-established relation is the fundamental plane (FP), which links the radio luminosity, X-ray luminosity, and black hole mass of accreting black holes. It encapsulates the coupling between the accretion disc and the jet, unifying X-ray binaries and active galactic nuclei under a common disc-jet framework across mass scales. Radio-quiet and radio-loud AGNs occupy distinct FPs, with the former exhibiting systematically higher Eddington ratios than the latter. As shown in the middle and right panels of Figure 7, the *Forges* lie on the FP of radio-quiet AGNs, consistent with their radio loudness values of $R < 10$. This further supports the interpretation that their central AGNs are approaching the typical quasar regime.

UV variability

JWST Cycle 1 COSMOS-Web program⁵⁵ and the COSMOS-3D program obtained NIRCcam images in F115W and enable us to probe the rest-frame 3000 Å variability on a rest-frame timescale of 200 days. We performed F115W-band photometry at the two epochs using a small aperture radius of 0".15 to isolate the variability of the central region. For *Forge I*, we obtain 26.15 ± 0.37 and 26.54 ± 0.43 mag in the two epochs, respectively. For *Forge II*, the corresponding values are 24.61 ± 0.20 and 24.68 ± 0.21 mag. The total photometric uncertainty includes contributions from the source Poisson noise, the background noise within the aperture, and the uncertainty in the background estimation from the sky annulus, and is expressed as

$$\sigma_{\text{flux}} = \sqrt{\text{flux} + N_{\text{aperture}} \sigma_B^2 + \frac{N_{\text{aperture}}^2 \sigma_B^2}{N_{\text{annual}}}},$$

where N_{aperture} and N_{annual} are the numbers of pixels within the source aperture and sky annulus, respectively, and σ_B is the standard deviation of the background within the annulus. The variability significance between the two epochs is quantified as

$$\text{SNR}_{\text{var}} = \frac{|\Delta \text{flux}|}{\sqrt{\sigma_{\text{flux, Epoch1}}^2 + \sigma_{\text{flux, Epoch2}}^2}}.$$

This estimation yields low SNR_{var} values of 0.68 and 0.26 for the two *Forges*, indicating no apparent UV variability.

Number density

The wavelength coverage of the F444W slitless spectra from COSMOS-3D enables detection of He I at redshifts $z = 2.5\text{--}3.7$. We identify all He I-emitting LRDs within the available COSMOS-3D area (9/10 of the whole survey observed as of November 2025; effective coverage of $\sim 0.28 \text{ deg}^2$) to estimate the fraction of LRDs caught in the transition phase at this epoch. Our parent sample originates from the COSMOS-Web photometric catalog⁹⁸ and includes only those objects with detected emission lines of $\text{S/N} > 3$ in the COSMOS-3D coverage. We select compact object with $f_{0.3''}/f_{0.15''} < 1.8$. For each object, we fit the He I emission line with one narrow Gaussian component ($\text{FWHM} < 500 \text{ km s}^{-1}$) or one broad Gaussian component ($\text{FWHM} > 1000 \text{ km s}^{-1}$) plus one narrow Gaussian component ($\text{FWHM} < 500 \text{ km s}^{-1}$). To compare the quality of these two types of fitting, we calculate the Bayesian Information Criterion (BIC) parameter, defined as $\text{BIC} = \chi^2 + k \ln n$, where k is the number of free parameters and n is the number of data points. We select broad-line objects with $\text{BIC}_{2\text{Gaussian}} - \text{BIC}_{1\text{Gaussian}} < 5$ and a broad-component S/N larger than 5. We visually inspect all the broad-line objects to remove the contamination from nearby objects and identify the He I lines based on the photometric redshift and multiple emission lines around He I. We then measure their UV/optical continuum slopes and selected V-shape objects following the criteria of Ref.⁴. This procedure yields seven LRDs (including *Forges*) with $M_{5100} = -25.2$ to -20.1 , implying that $\sim 30\%$ of He I-emitting LRDs at $z \sim 2.5\text{--}3.7$ appear to be in the transition stage. The evolutionary state of the remaining population is still uncertain. Interestingly, the other five LRDs show no X-ray or radio detections and lack elevated MIR emission, consistent with the properties of typical LRDs. Only one of them exhibits a blueshifted He I absorption line, but that feature is much weaker than in *Forges*'. These contrast between *Forges* and the other five He I LRDs further supporting the uniqueness of *Forges*.

We put the inferred number density of He I LRDs and transitioning LRDs in the context of number density evolution of LRDs and quasars in Extended Data Figure 8. The error bars of our estimated

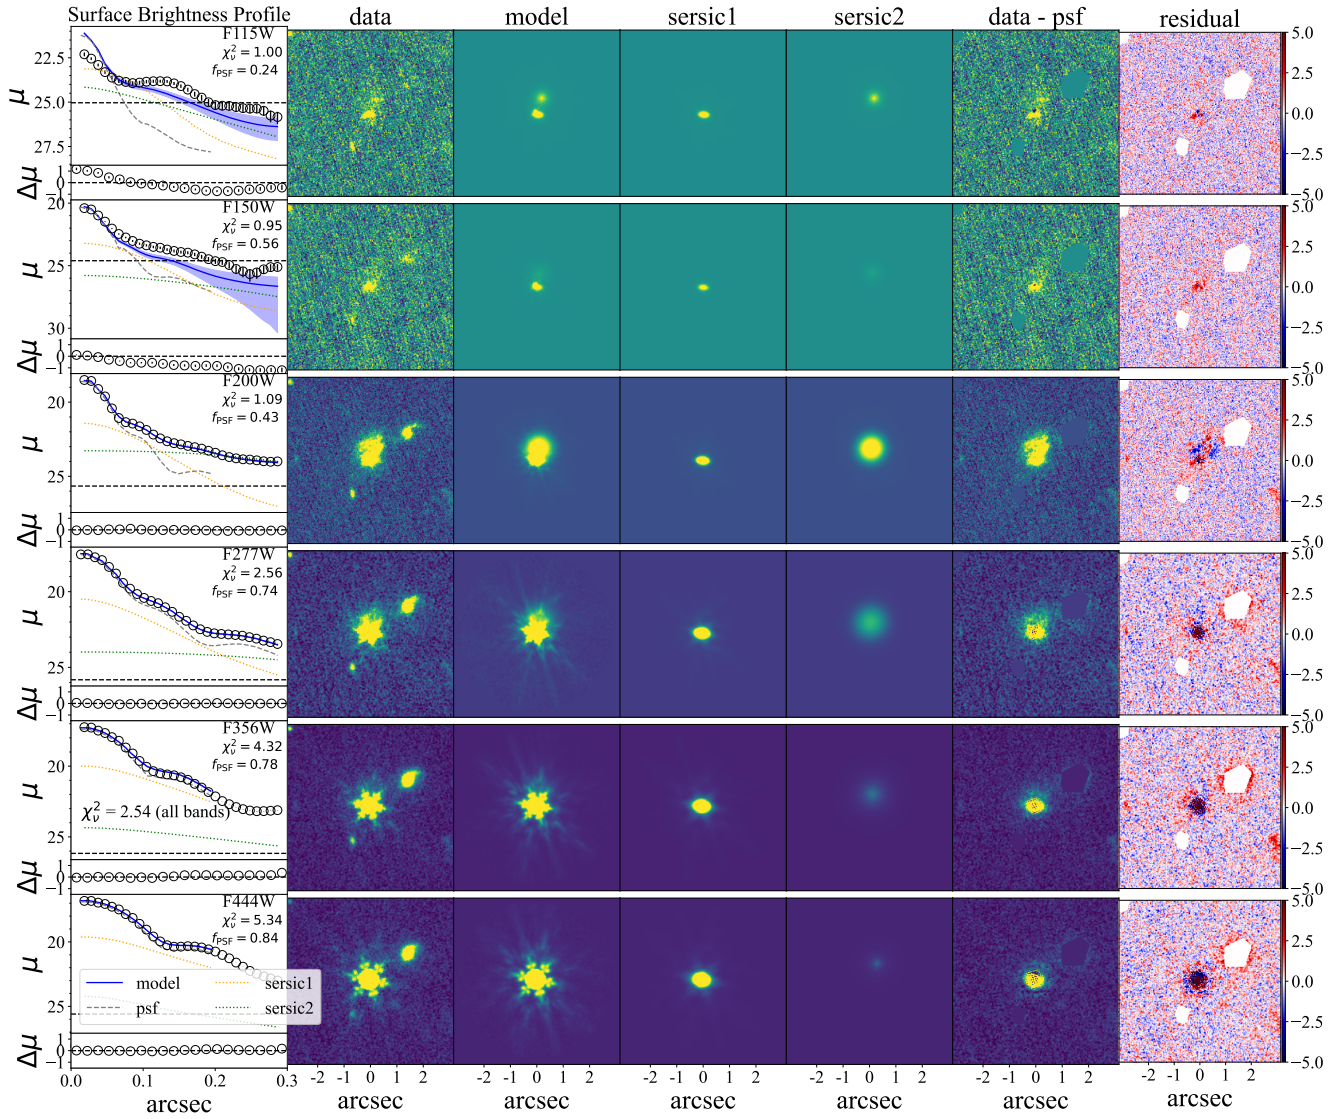

densities represent Poisson uncertainties. For comparison, we adopt the quasar number density from Ref. ⁹⁹ with $M_{\text{UV}} < -21$, which corresponds to $M_{5100} < -20.5$ for a typical quasar SED. Our estimated LRD number densities at $z \sim 2.5\text{--}3.7$ are smaller than Ref. ²³ and broadly consistent with the prediction of the log-normal model ²⁵. The measurements from Ref. ²³ are based solely on photometry and do not account for the presence of broad spectral lines, and may therefore include some contamination. At this redshift range, the LRD number density is comparable to that of quasars, while transitioning LRDs constitute a small fraction of the population, in good agreement with the transition scenario we proposed.

Extended Data Table 1. Emission and Absorption Line Properties. All EWs are in the rest frame. Velocities are relative to the systemic redshift, with positive values indicating redshifted and negative values indicating blueshifted.

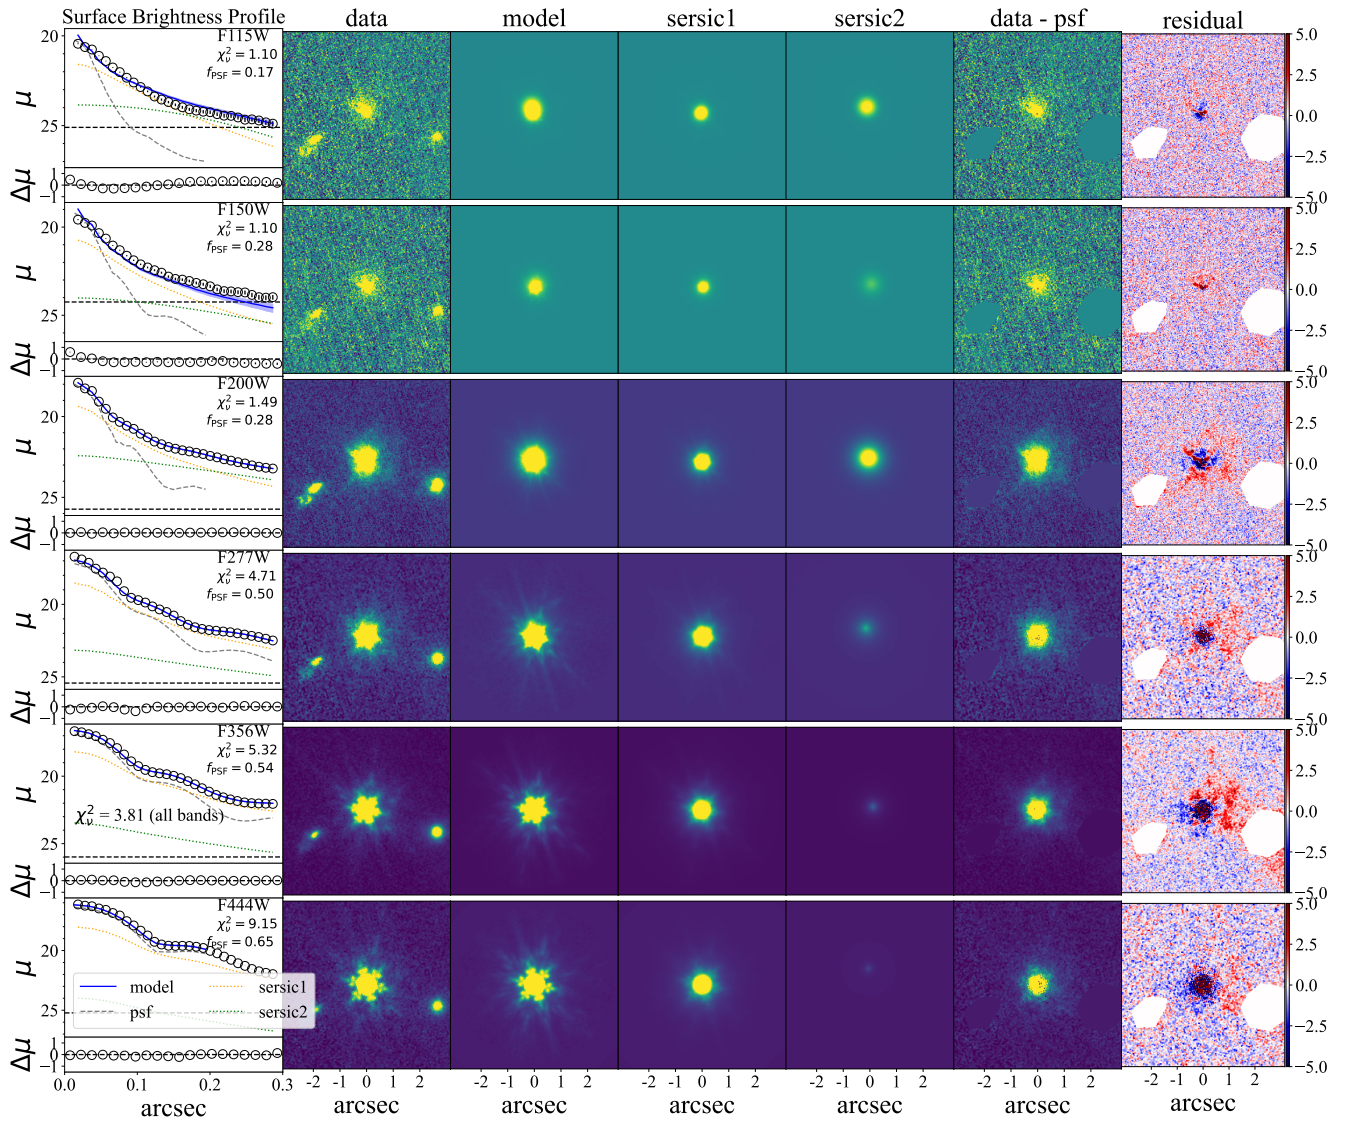

Feature	Component	Parameter	<i>Forge I</i>	<i>Forge II</i>

Extended Data Figure 1. Two-dimensional image decomposition of the *Forge I* with `galfitM`. For each JWST/NIRCam band (F115W–F444W), panels from left to right show the surface-brightness (μ , in the units of mag arcsec^{-2}) profiles, data, best-fit model, individual Sérsic components, data - PSF, and residuals/error that are stretched linearly from -5 to 5 . The reduced χ^2 values and the PSF flux fractions (f_{PSF}) are indicated for each band. The χ^2 value for all eight bands is given in the lower-left corner of the panel for F356M.

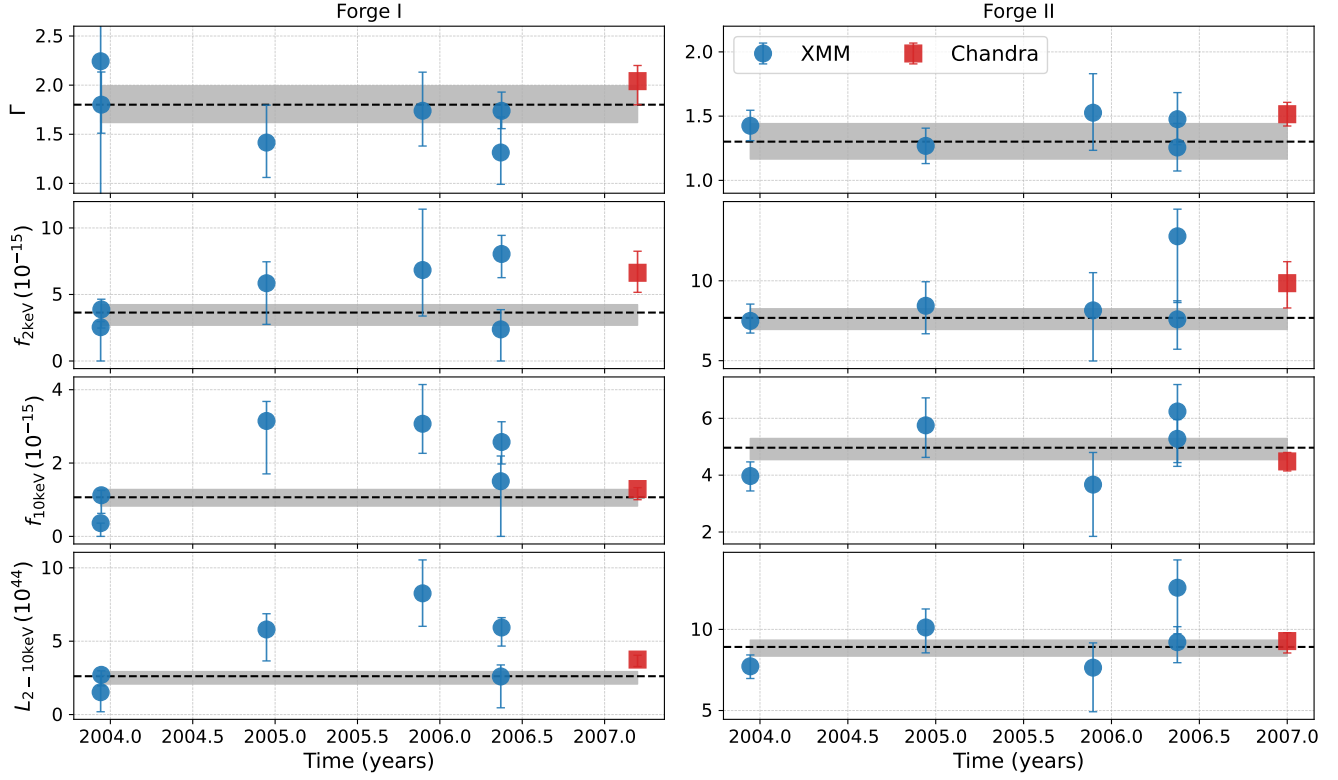

Extended Data Figure 2. Same as Figure above, but for the *Forge II*.

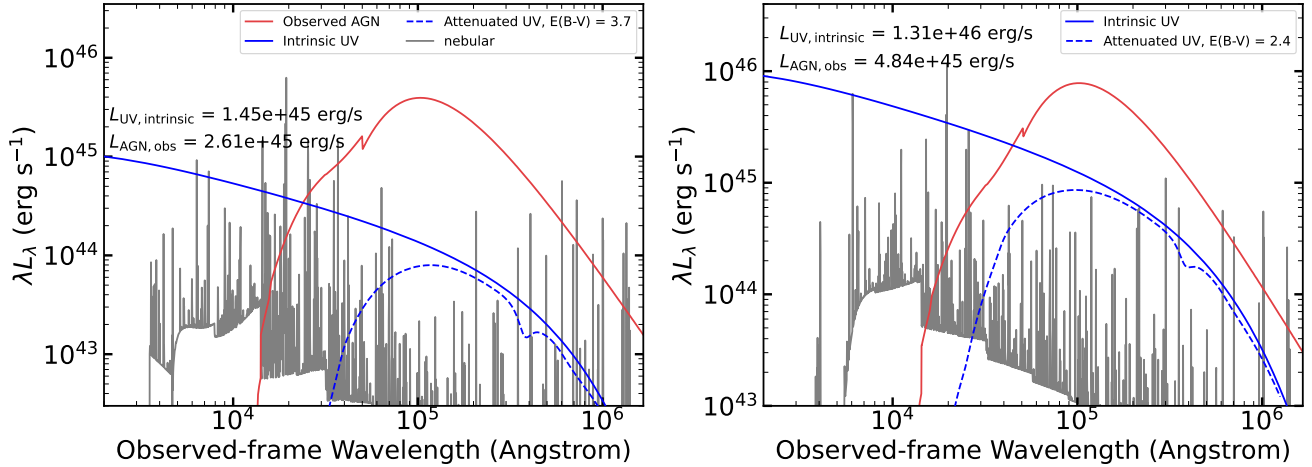

Extended Data Figure 3. Best-fit SED modeling. In each figure, the top panels show the observed photometry (open circles with error bars; upper limits are marked by downward triangles) together with the best-fit models (solid curves). The photometry is decomposed into AGN, host-galaxy, and nebular components in the rest-frame UV–near-IR, whereas only the total fluxes or upper limits are presented in the mid- to far-IR because of the limited spatial resolution. The AGN model consists of an LRD model with optically thick photospheres around a super-Eddington accreting black hole⁴⁰, combined with one blackbody at characteristic temperatures of $T \sim 500$ K. The bottom panel shows the residuals, defined as $(\text{Observed} - \text{Model})/\text{Observed}$, for the AGN, galaxy and nebular components separately.

Extended Data Figure 4. The combined XMM-Newton spectra of the *Forges* overlaid with the best-fit power-law+zphabs models. The bottom panels show the ratios of the spectral data to the best-fit models. The EPIC pn (black), MOS1 (orange), and MOS2 (blue) spectra were jointly fitted. For *Forge II*, a Fe $K\alpha$ line at a rest-frame energy of 6.4 keV (observed-frame 1.63 keV) is detected, with its position indicated by the red dashed line.

Extended Data Figure 5. Variability of the photon index (Γ), X-ray flux densities at rest-frame 2 keV and 10 keV, and the 2–10 keV X-ray luminosity. The black dashed lines and gray shaded regions represent the measured values and errors of the stacked XMM-Newton spectra.

Extended Data Figure 6. The intrinsic UV SED of the central AGN inferred from CLOUDY fitting of the ionized nebular emission of *Forge I* (left) and *Forge II* (right), compared with the attenuated UV SED assuming the Galactic dust-to-gas ratio and Calzetti dust extinction law⁹⁰. The gas column density N_{H} is derived from X-ray spectral fitting. The absorbed UV energy and the observed reprocessed optical–IR energy are indicated, showing comparable magnitudes.

Extended Data Figure 7. **Left:** Locations of the *Forges* on the $\alpha_{\text{OX}}-L_{2500}$ plane. Blue symbols show the observed total L_{2500} , which is dominated by host-galaxy and off-center nebular emission, while red symbols indicate the intrinsic L_{2500} inferred from the ionized nebular emission. The $\alpha_{\text{OX}}-L_{2500}$ relation from Ref. ¹⁰⁰ is shown as the solid line, with the dotted lines representing the 1, 2, 3 σ scatter of the relation. The small grey dots and downward arrows represent the α_{OX} values and upper limits of the quasar sample of Ref. ¹⁰⁰, respectively. **Middle and Right:** Locations of the *Forges* on the fundamental plane ³⁸, where L_R is the rest-frame 5 GHz radio luminosity (in units of erg s^{-1}), L_X is the rest-frame 2–10 keV X-ray luminosity (in units of erg s^{-1}), and M_{BH} is the black hole mass (in units of M_{\odot}), shown for radio-quiet AGNs (middle panel) and radio-loud AGNs (right panel). The dashed black line in each panel represents the 1:1 relation.

Extended Data Figure 8. Number density evolution for LRDs with $M_{5500} < -20.5$. The solid gray and red dots show the He I LRDs and transitioning LRDs at $z = 2.5-3.7$ estimated in the COSMOS-3D footprint, whose error bars represent Poisson uncertainties. These are compared with literature measurements ^{4,23,101}, a log-normal LRD evolution model ²⁵ (dashed purple line), and the quasar number density evolution with $M_{\text{UV}} < -21$ from Ref. ⁹⁹ (solid black curve).
